The line planning problem consists of finding a set of lines to serve as well as which frequencies to operate in a public transport network. Including frequency-setting gives an indication of a timetable and allows for a better approximation of the operator costs and passenger service, however, it makes the problem difficult to solve for real-life instances. In this talk, we present an exact, more scalable solution method for solving line planning problems. The problem is modelled using a mixed integer programming formulation, which minimizes both operating costs and passenger costs subject to budget and capacity restrictions. The passenger cost is the perceived travel time considering frequency-dependent transfer and waiting time costs. The proposed algorithm starts with a reduced representation of the problem. It iteratively adds frequencies to the model by utilizing the internal trade-off between the two conflicting objectives in the problem. We present a computational study based on both well-known artificial and real-world problems. Our results show that the algorithm is able to find solutions faster and without explicitly creating the complete formulation.

3 - A Genetic Algorithm with Several Fitness Functions for Line Planning

Maarten Wens, Pieter Vansteenwegen

Most algorithms solving the transit network design problem (TNDP) or Line Planning Problem (LPP) focus only on one objective function and the provided input parameters, e.g. the distance matrix. By changing these parameters or the objective, algorithms can escape from local optima. In this work, a genetic algorithm is created that includes several alternative fitness functions across a population, focusing on different aspects of a solution. This can range from putting a focus on low-demand areas to putting a focus on minimising the transfers. Our implementation introduces the concept of sub-populations, which work in parallel and aim for optimal solutions for slightly different fitness functions. These sub-populations share their found improvements, allowing a synergy between them. When this idea is implemented in an algorithmic framework for network design, the results improve the current literature for all Mumford networks, a commonly used benchmark instance. For these benchmark instances, the objective function value, considering the average travel time of passengers, is reduced by (1, 0.5, 3, 2.5)%. Not only does this algorithm improve current benchmark results, but the output contains a set of high-quality, yet substantially different networks, which is interesting for transport operators and for the follow-up research we have in mind. Finally, this algorithm is successfully used in a case study in cooperation with the main public bus operator of Flanders, Belgium.

4 - An alternative network representation to speed up network design

Pieter Vansteenwegen, Dilay Aktas

Given the infrastructure network and an origin-destination demand matrix, the set of lines of a bus, train or tram system is optimized with the Transit Network Design Problem (TNDP). When addressing the TNDP with passenger travel time in mind, the passenger assignment problem (PAP) needs to be addressed. Due to the complexity of the TNDP, typically bi-level optimization models and/or metaheuristics are used, where the PAP is solved every time a line plan is evaluated. In doing so, the transit network needs to be expanded, typically with a so-called 'Change-and-Go' (CNG) network with dummy transfer nodes, in order to model transfer penalties as part of the passenger travel time. Then, the all-pairs shortest path problem needs to be solved for this expanded network representation, which is by far the most time consuming part of the algorithms. To overcome this, we present a much more efficient network representation, the 'Direct Link Network' (DLN), where additional edges are added instead of additional nodes. We compare the computation time required to solve the PAP by using CNG and DLN on the most commonly used benchmark networks and several real-life networks. The results show that with the DLN representation, the PAP can be solved on average 350 times faster than with CNG. Consequently,

DLN can significantly speed up all TNDP algorithms that solve the PAP over and over when designing a public transport network.

1 - The McNugget-Knapsack Connection: Refining Upper Bounds on the Frobenius Number with Operational Research Applications

Aled Williams, Daiki Haijima

We study the classical Frobenius problem, which seeks to find the largest integer that cannot be represented as a nonnegative integral combination of given relatively prime positive integers, termed the Frobenius number. The Frobenius problem is known by other names within the literature such as the money-changing problem, the coin problem, the chicken McNugget problem and the Diophantine problem of Frobenius.

The Frobenius number is an important quantity in operational research where, from a geometric viewpoint, it is the maximal right-hand side such that the corresponding knapsack problem is integer infeasible. Further, given that the knapsack problem is NP-hard, there is a rich history on this problem. Note that computing the Frobenius number in general is NP-hard and, as such, there has been a much research into producing upper bounds on the Frobenius number.

The main contributions are observations regarding a previously known upper bound. In particular, we observe that a previously presented argument features a subtle error that alters the value of the bound. Despite this, we show that the error does not impact upon on the bound's validity, although it does impact on its tightness. We compare the relative tightness of the corrected upper bound with the original. In particular, we show that the updated bound is tighter in all but only a relatively "small" number of cases using both formal and simulation-based techniques. This is joint work with Daiki Haijima.

2 - Evaluating approximate symmetries in complex brain networks

David Hartman, Anna Pidnebesna, Aneta Pokorna, Jaroslav Hlinka

Complex networks representing structural properties of natural systems exhibit characteristics such as small-world or scale-free. However, the symmetry of such networks has not been studied much until recently, although some networks, such as the human brain, have symmetries directly embedded in their structure, or such symmetry is an indicator of their specific state. In a recent study, however, it was shown that non-trivial symmetries based on graph automorphisms exist in general complex networks representing real-world systems. Nevertheless, due to the uncertainty of determining the edges of such a network, it is necessary to consider approximate symmetries, as was shown in a recent study by Liu 2020, where the image of the resulting automorphism may show inconsistencies for several pairs. However, the proposed optimization method has shortcomings, such as, for example, the instability of the results, relatively small radius of search, and not considering fixed points. In this paper, we consider adopting the method recently developed for treating the Graph Matching Problem and propose an alternative method that addresses some of the shortcomings of the approach mentioned above. In addition, we propose a scheme for testing the approximate symmetry methods using different random networks reflecting the approximate symmetry in the network representing the complex networks with emphasis on the human brain.

3 - Promoting Student Wellness through Maximally Diverse Grouping with Acceptance Relation

Lior Aronshtam, Tammar Shrot, Hadassa Daltrophe

The problem of partitioning objects into different groups according to predefined attributes has been extensively studied in OR research. A field in which grouping is frequently referenced is education, where students need to be divided into groups for collaborative learning. A major factor contributing to successful learning is student wellness, which is influenced by the group's social structure. Hence, the ability of the student to choose their group mates is crucial in the grouping process. Yet, students' wellness is not the only important factor in building groups. An additional important factor is the diversity of the group members in various features. Many studies in OR approached the grouping problem using the known setting of the maximally diverse grouping problem (MDGP), which does not concern student social preferences.

In this study, we consider a new version of the MDGP, in which each student declares a set of acceptable students, and the goal is to find a maximal diversity partition to groups in which every student is grouped with at least one of its acceptable mates. We formally defined the problem, studied its complexity, and found that a solution does not always exist and it is NP-complete. Driven by real-world challenges, we used students' acceptable choices to structure mid-school classes and project groups in academic courses using an integer programming solver. We analyzed the existence of a solution in each case and its quality.

4 - Algorithm for Solving Combinatorial Optimization Problems with Fractional-Linear Objective Functions

Liudmyla Kolietchkina

This annotation proposes an algorithm for solving combinatorial optimization problems with fractional-linear objective functions. Such problems are ubiquitous in diverse domains including operations research, scheduling, and network optimization, where the goal is to find an optimal arrangement of elements from a finite set. The proposed algorithm uses the properties of combinatorial configurations of permutations and their graphs. The essence of the algorithm is to perform the following steps: the coefficients of the numerator and denominator of the fractional linear function are determined, the elements of the permutation are specified; for a selected pair of adjacent permutations, the difference in the values of the linear fractional function is calculated; based on the calculated coefficients and signs of the differences, a structured permutation graph is formed, which allows you to analyze changes in the values of the objective function at the vertices of the graph; for the selected elements of the permutation in the graph, a Hamiltonian path is formed along which the values of the objective function change; extreme values of the objective function are calculated, which are achieved at the extreme points of the permutation graph.

This algorithm allows you to solve combinatorial optimization problems with fractional linear objective functions by analyzing the function values for various permutations and constructing a structured permutation graph.

Adya Pandey, Nomesh Bolia

Millets can significantly contribute to achieving certain Sustainable Development Goals (SDGs) namely SDG 2 (Zero hunger), SDG 3 (Good health and well-being), SDG 12 (Ensure sustainable production and consumption pattern), and SDG 13 (climate action). Traditionally a part of the Indian food basket, millets lost their share drastically since the Green Revolution due to the incentivization of other food grains. However, due to increasing malnutrition and environmental degradation, the Government of India is undertaking numerous initiatives to promote large-scale consumption of millets. To ensure a sustainable supply of millets, it is important to tackle the consumption barriers faced by the masses. The present study utilizes a stated preference survey to identify the consumption barriers and understand respondents' likelihood of increasing millet consumption if these barriers are eliminated or reduced. An online survey was conducted in March 2023 for the same. Based on the survey responses, consumer segmentation is done using non-parametric tests viz. Kruskal-Wallis and Mann-Whitney test followed by Post hoc Dunn Bonferroni's test. The results indicate demographic subgroups that have significantly higher likelihood of increasing their millet consumption when different strategies are implemented. The results of the study can serve as a baseline for millet-specific industry players and help them develop marketing tools incorporating features that help eliminate the barriers.

2 - Flexibility Focused Sustainable and Resilient Product Recovery Network Models

Jitender Madaan, Ekachidd Chungcharoen, Sanjeet Singh

Decision makers for adopting sustainability in their operations did not conventionally realize the environmental and socio-economic advantages of returns management. However, studies have shown sustainable investments in returns produce ecological improvements that can have considerable financial advantages (Win-win situation). However, comprehensive research is still required to achieve this sustainability to achieve economic and environmental paradigms. Research must focus on providing resilient models that demonstrate the competitive advantage companies can build by extracting value from product returns. It has also been realized that to make Enterprise Systems (ES) more sustainable, responsive, and competitive, considerable research effort is required to demonstrate performance improvement forward (i.e. flow of materials, products, and information from producer to consumer) as well as in reverse flows (referring to both recovery and return of products and information from consumer to producer). The tradeoffs between the performance objectives of both flows necessitate the development of enough process capabilities that can improve performance simultaneously. Flexibility can be seen as one such capability to enhance the resilience of value recovery flow systems. This is an effort to study and demonstrate economic performance through a resilient product recovery system under various scenarios, which is the primary subject of the paper.

3 - Examining the Influence of Sustainable Operational Practices on Corporate Performance: A Study on Automotive Sector

Vaishnavi Pandey, Vijayta Fulzele

This paper applies Institutional theory to benchmark sustainability (via Return-To-Scale) and identify key factors enhancing market capitalization and shareholder equity through Panel Data Analysis. This study uses benchmarking analysis- to study the Return to Scale of 16 global automobile firms, specifically utilising Data Envelopment Analysis (DEA-VRS) using MAXDEA software and Panel Data Regression Analysis using STATA software for Years 2019-2022. The findings suggested that Volkswagen (1464.09) has the highest and positive return to scale, followed by Kia (39.19), Ford (19.14), Volvo(13.73), Maruti Suzuki (7.97), Mercedes (4.60), Honda (2.06), Tata Motors (1.83) respectively. On the other hand, Nissan (0.60), Hyundai(0.48), and Toyota (0), respectively, have constant Return to Scale. Furthermore, General Motors (-0.06), Mahindra and Mahindra (-0.13), Isuzu(-0.69), BMW(-0.77), and Stellantis(-1.09) have negative Return To Scale. Panel Data Regression highlights that GHG emissions, Energy Consumption, Waste Generation, Total Assets, R&D, and Operating costs significantly affect Automobile firms' Market Capitalization. Gender diversity is entirely insignificant. GHG emissions, waste

generation, social contribution, total assets, and operating costs significantly affect Shareholder equity in the firm. Energy consumption and Lost-Time accidents minimally affect shareholder equity. Water Consumption, Gender Diversity, and R&D investment are insignificant for Shareholder Equity.

4 - Green Shopping Online: Boosting Eco-Friendly Choices Through Integrated Product Strategies

Raziyeh Reza-Gharehbagh

This study presents a novel approach to online retail sustainability, embedding eco-labeled products alongside conventional offerings to stimulate sustainable consumer behavior. Inspired by the EU eco-label strategy, our framework aims to empower consumers while promoting sustainable purchasing decisions. We examine the nexus between consumer utility, environmental awareness, and online retailers' marketing efforts, strategically enhancing the visibility of eco-labeled products. Central to our analysis is the certification landscape, where retailers navigate between developing their own certifications and utilizing external standards. Employing game theory, we analyze retailers' optimal strategies under different certification policies. This research not only introduces a new paradigm in online retail sustainability but also provides strategic insights crucial for future sustainability initiatives in the digital marketplace.

Chair: Marjan van den Akker

1 - A Strong Formulation for the Train Dispatching Problem and its Solution

Maik Schällicke, Karl Nachtigall

Disruptions in the operational flow of rail traffic can lead to conflicts between train movements, such that a scheduled timetable can no longer be realised. This is where dispatching is applied, existing conflicts are resolved and a dispatching timetable is provided. In the process, train paths are varied in their spatio-temporal course. This is called the train dispatching problem (TDP), which consists of selecting conflict-free train paths with minimum delay. Starting from a path-oriented formulation of the TDP, an IP is introduced. The IP selects the best of all potentially possible train paths via binary decision variables, which results in a big number of variables, so column generation is used to solve the problem. Instead of modelling pairwise conflicts, a stronger formulation is achieved by cliques formulated over the complete train path. The resulting pricing problem is a hard problem, because the shadow prices of the conflict cliques must be taken into account. When constructing a new train path, it must be determined whether this train path belongs to a conflict clique or not. This problem is tackled by a MIP. The methodology is tested on instances from a dispatching area in Germany. Numerical results show that the presented method achieves acceptable computation times with good solution quality while meeting the requirements for real-time train dispatching.

2 - A real-world locomotive scheduling problem with stochastic travel times and buffers

Kanchan Joshi, Jan Fabian Ehmke

Railways, offering environmental efficient transport services, are a potential alternative to roadways. However, the increasing complexity of rail networks and interactions between infrastructure, resource planning, particularly locomotive scheduling, and personnel deployment, poses significant challenges. Railway companies use optimization techniques to generate circulation plans, promising efficient resource

utilization. Nonetheless, these plans are often deterministic and ignore information on disruptions arising from delayed crew, crowded infrastructure and breakdowns. As a consequence, ad hoc short-term rescheduling and adjustments are necessary, resulting in economic penalties and a negative impact on perceived service quality. In this paper, we aim to determine reliable locomotive schedules that minimize the number of locomotives and empty-run distances using a time-space network formulation. To generate reliable plans, we design and include buffers considering stochastic travel times. We evaluate the effect of inserting these buffers on the number of locomotive and empty-run distances for real-world Austrian railway use cases. At the same time, we assess schedule reliability through feedback from simulations. The trade-off between reliability, the number of locomotives, and empty-run distances can offer valuable insights to planners seeking to address disruptions without stressing already constrained infrastructure.

3 - Simulated Annealing to Solve the Integrated Airline Fleet and Crew Recovery Problem

Philip de Bruin, Marjan van den Akker, Kunal Kumar, Lisanne Heuseveldt, Marc Paelinck

Airline operations are prone to delays and disruptions, since the schedules are generally tight and depend on a lot of resources. Since the COVID pandemic, most airlines also have shortages of these resources, making the problem worse. In case of disruptions, such as aircraft breakdowns or crew sickness, the schedule needs to be adjusted. This means either changing resource assignments or delaying or cancelling flights. Such adjustments need to resolve a disruption while minimizing overall costs and impact on passengers. For practical use, this needs to be done as close to real-time as possible.

We focus on both the aircraft and crew schedules. Resolving disruptions for these can be done sequentially, but decisions in one problem may lead to more conflicts in the other. Thus, we take an integrated approach. Such an approach comes with computational challenges, especially because of the runtime required for practical use.

For this, we develop a local search algorithm based on simulated annealing. Where, in order to not spend time on making changes in unaffected parts of the schedule, we test different neighbour generation and selection approaches that steer the local search into resolving these disruptions more directly. The work is done in collaboration with and with data from KLM Royal Dutch Airlines.

We show that our approach is very fast, achieving runtimes well below a minute. Furthermore, we also show that the disruptions are resolved in a cost-efficient manner.

4 - Disruption Management in Airline Luggage Handling using Local Search

Lisanne Heuseveldt, Marjan van den Akker, Ali Poursaeidesfahani, Philip de Bruin, Kunal Kumar

Flight times are influenced by many factors. Examples are weather conditions or congestion at the airport, leading to ATC delays or limited gate availability. These factors influence the arrival time at the gate, which can thus vary considerably.

Since COVID, ground personnel for loading and unloading luggage to and from an aircraft are scarcely available, so we need to deploy them efficiently. Because of this scarcity, the process is highly sensitive to the variation of arrival times. To deal with this, a fast algorithm to (re)schedule the allocation of the luggage handlers is required.

We consider the assignment of luggage handlers to tasks arising from arriving and departing aircraft on the day of operations. We aim to make real-time updates that solve disruptions and are cost-efficient. This problem can be considered as a technician routing and scheduling problem (TRSP), where we consider teaming, skill and time window constraints in a dynamic setting. We have to synchronise multiple tasks corresponding to the same flight, which is a new aspect in regard to TRSP literature. Our algorithm proposes delays or cancellations of flights; these levers are often unexplored from a ground operations perspective.

We solve these disruptions using a simulated annealing algorithm, with the original solution as a starting state. This solves the problem in real-time. We will present computational results from experiments with real-life data provided by KLM Royal Dutch Airlines.

1 - Impact of Foldable Container Implementation on Vehicle Operations: Focusing on Folding Time

Koichi Shintani, Hikaru Takashima, Kenichiro Nagaiwa, Etsuko Nishimura

The introduction of foldable containers is anticipated to reduce the number of vehicles required for repositioning empty containers. However, when using foldable containers, folding time (FT) is necessary in addition to waiting time (WT) until the same number of containers as the stacking tier accumulates. These factors could potentially decrease the operational efficiency of vehicles and containers. Therefore, this study focuses on the relationship between FT, WT, and the operational status of an inland depot, employing a stochastic simulation approach to verify how efficiently foldable containers can facilitate empty container repositioning by vehicles. The results of numerical experiments reveal that the variation in FT duration significantly impacts the economic viability of foldable containers.

2 - Hub-and-spoke container shipping network design under uncertainty

Cihan Butun, Sanja Petrovic, Luc Muyltermans

Containerized shipping has recently been deeply affected by events such as Covid-19 pandemic and regional wars. These events led to unexpected slumps or surges in demand, hampered cargo handling capacity of ports, and compelled liners to streamline their services to mitigate operational difficulties and logistical hurdles. In this paper, we address the design of a hub-and-spoke container shipping network by assuming that the values of origin-destination cargo demands and port capacities are imprecise. The imprecision in these parameters is represented with trapezoidal possibility distributions. The problem involves the location of transshipment hub ports, allocation of non-hub ports, and routing of cargo flows in the resulting network so as to minimize the expected network cost. We formulate the problem as a possibilistic mixed integer linear programming model and convert it to a chance constraint model using a fuzzy measure. To solve the chance constraint model, we develop a Tabu Search algorithm. In addition, we design an upper bound procedure that decomposes the problem into three subproblems and solves them iteratively. The computational experiments using the data of 50 ports in the Mediterranean show that the proposed solution method finds optimal or near optimal solutions in a very short computational time. In addition, analysis of the resulting networks provides important insights into the impact of uncertainty on the network cost and number of hubs.

3 - Optimizing Urban Parcel Logistics: An ALNS-based approach to combine tradition and technology

Barbara Himstedt, Frank Meisel

In the past, urban parcel delivery was dominated by diesel-powered vans. However, with society's growing awareness of sustainability, parcel delivery services are now encouraged to adopt innovative and environmentally friendly systems. As a result, cargo bikes, robots, and drones are investigated as potential alternatives. But relying on a single delivery system may not always be practical, as not all customer locations are suitable for these new technologies. However, it could prove beneficial to combine them with the traditional method to ensure an efficient and cost-effective delivery process. To address these issues, a mathematical optimization model for managing urban parcel

logistics with two echelons is proposed, which can be used both independently and in combination with alternative means of transportation. An Adaptive Large Neighborhood Search is presented to analyze realistic urban delivery areas, and insights into its performance and the practicality of integrating combined fleets are provided. A case study from Hamburg, Germany, shows that labor costs are a key factor influencing the effectiveness of delivery vehicles. In addition, the strategic value of integrating robots and drones into delivery systems becomes clear, even if only a proportion of customers opt for these new means of transportation. These findings provide valuable recommendations for stakeholders considering the introduction of innovative parcel delivery systems tailored to urban environments.

1 - One-to-Many Stable Matching for Integrating Ridesharing and Public Transit on a Mobility-as-a-Service Platform

Yating Wu

Mobility-as-a-Service (MaaS) is an innovative user-based mobility system that offers users a one-stop personalized service by seamlessly integrating multi-modal transport services. MaaS has become increasingly popular and is reshaping travel behavior. However, MaaS is essentially a decentralized user-centric system, which is challenging to operate since both service providers and travelers are self-interested. We address this problem by studying a MaaS system that integrates one-to-many ridesharing and public transit through a digital platform that flexibly matches riders with drivers and/or public transit. We generalize the classic one-to-many stable matching concept to incorporate the users' preferences in the planning of daily operations. The stable matching problem formulated as an integer program typically includes a huge number of matches and complex stability constraints. We develop a computationally efficient algorithm that integrates Lagrangian relaxation with column-and-row generation procedure to solve the model. Theoretical properties of the model and algorithm are investigated. We also test the algorithm on a real-world case and show that the algorithm converges quickly. Extensive computational experiments reveal various new managerial insights into social welfare, transit usage, users' savings, matching rates, and travel detour.

2 - The electric dial-a-ride problem with capacitated charging stations, multiple depots, and customer rejection

Yumeng Fang, Tai-yu Ma, Francesco Viti

Integrating mass transit with demand-responsive service is challenging due to joint optimization of bus routes and multimodal customer trips. State-of-the-art mixed-integer-linear programming (MILP) approaches can solve the problem exactly for less than 10 requests (Posada et al. 2017). This is due to the cumbersome modeling of partial routes of the mass transit network, where the number of arcs expands rapidly with the network size. Besides, using electric vehicles in this problem leads to additional complexity because of charging scheduling and capacitated charging station constraints. This study proposes a novel MILP formulation of an electric integrated dial-a-ride problem with multiple depots and capacitated recharging stations to minimize overall system costs considering transfer synchronization and customer rejection. To address the abovementioned issues, we use time-dependent shortest paths on transit networks to substantially reduce redundant decision variables. With a four-hour computational time limit, we test the

model up to 20 requests with different initial battery levels of vehicles. Results show that this model can solve the problem optimally around 95% faster and to a larger problem size if compared to Posada et al. (2017). A more compact arc-based formulation is developed concerning capacitated charging stations. The numerical results can reduce up to two-digit computation time compared to the state-of-the-art arc-based method.

3 - Enhanced analysis for more sustainable traffic systems through Two-Step-SDP

Eloisa Macedo, Paulo Fernandes, Jorge Bandeira

The EMBRACER Project focuses on improving the interconnection with urban and rural areas and achieve seamless intelligent climate-resilient regional and local intermodal mobility. Under this framework, digitalisation and traffic/transport data are essential to promote more sustainable mobility alternatives and satisfy citizens mobility needs. Data-driven knowledge allows for more informed and effective decision-making, both at a strategic and operational level. In this context, data analysis tools play a relevant role. We will focus on the potential of the Two-Step-SDP methodology for analysing vehicle dynamics data and gaining insights regarding traffic-related impacts. The technique is suitable for performing data clustering and dimensionality reduction, has shown superior performance to analogous methodologies, and it is implemented as an open-source tool. In particular, it considers the clustering problem of objects and attributes formulated as nonlinear SDP-based models and, due to their nature, it requires the use of Linear SDP relaxations and an approximation algorithm to obtain their solution. This methodology was applied to different sets of vehicle dynamics data and it revealed to enable a more detailed analysis of the traffic-related impacts. Analysing traffic-related data allows policymakers to make evidence-based decisions to improve the sustainability of transport systems and can then, implement targeted interventions to more sustainable mobility solutions.

4 - Traffic Distribution for Sustainable Intercity Corridors: A Mixed Conventional and eCAV Scenario

Jorge Bandeira, Luis Pereira, Eloisa Macedo

In the scope of the EMBRACER Project, the study explores integration of connectivity and automation in transport, emphasizing the challenges of managing the coexistence of conventional vehicles and connected and automated vehicles (CAVs). Optimising traffic flow in a mixed environment (different vehicle classes, automation levels, propulsion technologies, and kinematics) is crucial to realize the full potential of CAVs. Intercity corridors, with parallel routes, offer a controlled environment to examine the complex interplay of traffic flow, demand, network capacity, and demand management strategies. The study explores how optimising traffic distribution across parallel inter-urban routes can reduce travel time and environmental impacts, considering current traffic scenario and projecting effects of a 30% penetration of electric CAVs. The study employs field data (traffic volume, fleet composition, travel time, GPS data), microscopic traffic modeling to simulate existing conditions and incremental demand, and VSP methodology for emissions modeling. External costs are monetized based on greenhouse gas emissions and air pollution, enabling multi-objective optimisation. Results show a nonlinear impact of CAV integration, with benefits influenced by route characteristics and traffic demand. While widespread electric vehicle adoption significantly reduces emissions, optimised traffic distribution is essential for minimising traffic-related externalities in intercity corridors.

Market dynamics and implications for portfolio decisions

Stream: Modern Decision Making in Finance and Insur-

ance

Invited session

Chair: Jörn Sass

1 - Investor activity in EFSF/ESM secondary bond markets

Peter Schwendner

This study analyzes the secondary market dynamics of the European Financial Stability Facility (EFSF) and European Stability Mechanism (ESM) bonds from 2014 to 2020. Findings reveal increased activity of private sector investors, notably fund managers, with significant market risk exposure. The study examines the secondary bond market response to the initial impact of the COVID-19 crisis, observing investor behavior aligning with previous models of capital repatriation and subsequent re-entry. Additionally, it highlights a trend towards heightened activity in long-term market segments, spurred by a low yield environment, leading to the normalization of long maturities as liquid instruments. The paper also delves into the digitalization and automation of fixed income markets through electronic trading platforms, noting a gradual increase in electronic trading adoption, particularly among smaller ticket sizes. Despite this trend, central banks and public entities exhibit lower electronic trading shares, suggesting less pressure or motivation for adoption. Finally, the study explores the transaction network of primary dealers, revealing regional and institutional patterns that support liquidity maintenance strategies, emphasizing the role of local banks in stabilizing turnover volume and enhancing investor diversity across different trading platforms and countries.

2 - A Novel Approach to Thematic Portfolio Construction: Patent-based Investment Decision Making

David Jaggi, Alexander Posth, Carsten C. Guderian

In thematic investing, investors rely on long-term trends to detect and subsequently invest in what they assess as innovative companies with promising technologies. The established method for investors is to identify such companies via qualitative assessments or business sector classifications. Due to the established links between innovations, (new) technologies and patents, patent analytics has recently become an information source in thematic investing. However, there seems to be a mismatch between business sector- and technology-based classifications, which potentially affects (1) assessments in which technologies companies are active in and (2) the grouping of companies with supposedly similar technology profiles. With our research, we address these issues by analyzing the patent portfolios of the companies attributed to two Global Standard Classification Standard sectors. We examine the patent attribution profile vector of the companies in these sectors and compare them via the cosine distance metric and use clustering to group companies of high technological similarity and compare these to the S&P sectors. Further, we employ artificial intelligence tools to identify names for these newly generated clusters to ease comparability and interpret the results with a Sankey diagram analysis and a network graph analysis. Our findings yield implications for various decision-makers involved in thematic investment, including investors, corporate management, and policymakers.

3 - Stochastic dynamic optimization in strategic financial management

Antti Korhonen

Financial institutions play a major role in the economy and the society as a whole. Securing their stability and success is utmost important in the current unpredictable financial markets. Recent bank failures have demonstrated that financial crises tend to move fast in the global economy. Managing uncertainty is the key issue in volatile operating environments.

The talk will compare stochastic dynamic optimization methodology with simulation-based approaches which are still widely used in financial institutions. Mathematical optimization offers great benefits in solving complex real world strategic financial management problems. Only mathematical optimization is able to prepare institutions for diverse economic and financial market scenarios simultaneously and produce concrete decision recommendations. Simulation methodologies are insufficient for today's business decision making.

4 - Utilizing realized covariance estimators in finding safe haven evidence

Josip Arneric, Tea Šestanović

In the recent literature, an extensive application of realized covariance has been documented, which plays a key role in optimal allocation of various assets within contemporary portfolio management. The advantage of realized covariance, against alternative measures, is utilizing intraday high-frequency data observed over short intervals. Using this approach unknown integrated covariance matrix of a multivariate diffusion process can be estimated. This research is focused on modeling realized covariance between the EUROSTOXX50 index of Eurozone and gold, aiming to explore the characteristics of gold as a safe haven during crisis periods (including the COVID-19 pandemic and the Ukrainian war). In this context, the primary goal is to determine data properties, such as asynchronicity and the presence of microstructural noise and price jumps of return series. Subsequently, a suitable synchronization scheme and optimal sampling frequency will be chosen to eliminate these issues. To determine which estimator provides an unbiased and consistent estimation of realized covariance between the EUROSTOXX50 index and gold for investigating the safe-haven property, six covariance estimators will be compared: realized covariance (RCOV), realized bipower covariance (RBPCOV), realized threshold covariance (RTCov), realized outlying weights covariance (ROWCOV), robust realized two times scaled covariance (RRTSCOV) and Hayashi-Yoshida realized covariance (HYRCOV).

1 - Model for the Hospital Waste Collection Problem Considering Shared Load

Danna Manrique-Saavedra, Javier Arias-Osorio, Edgar E. Córdoba-Sarmiento

Hospital institutions navigate daily through critical risk activities, giving rise to the substantial generation of medical waste. These activities involve tailored control and monitoring procedures, encompassing logistical planning for the disposal and elimination of waste as an integral part of achieving their mission.

This ethos extends universally across industries and supply chains associated with healthcare. Consequently, this study delves into the pharmaceutical supply chain from the perspective of conscientious disposal practices. It categorizes waste into hazardous and non-hazardous types, linking them to designated treatment centers, whether those be recycling hubs or remanufacturing facilities. This classification takes into account the lifespan parameter for non-hazardous waste and mandates direct incineration for hazardous materials.

Finally, the study introduces an optimization model to scrutinize various hospital institutions as prolific sources of waste. These institutions would be visited by a diverse fleet of waste collection vehicles, equipped to handle both hazardous and non-hazardous waste. The model aims to address the primary queries of the Inventory Routing Problem (IRP): 1) When is the optimal time for visits? 2) What volume of waste should be collected? and 3) Which route should be pursued? Additionally, it incorporates an analysis of shared load considerations in each collection, particularly for smaller-scale instances.

2 - Tactical Planning Considering Different Levels of Flexibility for a Waste Collection Routing Problem

Christina Hess, Alina-Gabriela Dragomir, Karl Doerner

The planning of waste collection operations typically involves a series of tactical and operational decisions. This work is concerned with studying tactical decisions related to waste collection schedules and the use of intermediate facilities for unloading waste, while optimizing route planning at the operational level. The real-world inspired waste collection problem at hand can be modelled as a periodic vehicle routing problem with intermediate facilities. Vehicles based at a central depot collect waste from different locations and visit incinerators en route, when they are full, and at the end of each tour to replenish their capacity. The planning horizon is several days or weeks and, as plans should be repeatable, a periodic plan is established. In order to provide decision support to practitioners at both operational and tactical levels, we investigate more flexible collection schedules and flexibility in the use of intermediate facilities and their allocation to vehicle routes, considering minimum quotas and maximum capacities. The aim is to minimize overall transportation costs while avoiding overflows of the waste bins. The problem is solved using an adaptive large neighborhood search with problem-specific operators and a local search strategy. We present computational results on benchmark instances from the literature and on a set of real-world inspired instances from the city of Vienna showing the effects of allowing more flexibility in planning.

3 - A Roll-On Roll-Off Vehicle Routing Problem for Industrial Waste Collection: A Case Study in Northern Italy

Annarita De Maio, Francesca Vocaturo, Stefano Bortolomiol, Antonio Napoletano

This work tackles the issue of waste collection for a company situated in the Northern Italy. The project aimed to streamline waste collection planning through the implementation of a dedicated optimization engine. This problem involves collecting various types of waste from multiple customers, which then need to be transported to specific landfills. Compatibility constraints arise from the nature of the waste, the vehicle type, or the container loaded onto the vehicles. The collection process can unfold in various ways: containers may be loaded directly onto the waste management company's trucks and then returned empty to the original customer, or the loads (always equivalent to full containers) can be transferred onto the containers attached to the trucks and transported to the landfill. Moreover, the service must adhere to specific time windows associated with depot, customers, and landfills. The problem is defined as a roll-on roll-off pick-up and delivery problem with time windows. Given its complexity, a three-phase covering heuristic is developed. In the first phase, the algorithm clusters customers into subgroups; in the second phase, route generation takes place, while in the third phase, a modified version of the Chvátal heuristic is implemented to determine a feasible solution, with the aim of minimizing costs and ensuring the maximum coverage of served customers. The approach was tested using real data instances provided by the partner company.

4 - The Twin Rural Postman Problem

Marcos José Negreiros, Augusto Palhano, Nelson Maculan

This work shows a new arc routing problem where it is given a strongly connected weighted mixed graph and its required set of links (edges and arcs) and vertices, and a departure/end vertex. The Twin-Rural Postman problem (TRPP) is formed by at least two routes that depart and end at the same vertex v_0 , in such a way that both cover with minimum cost (distance) all the required links and vertices, and one of the RPP's route is performed in such a way that the other twin is no more than a maximum distance from the other, once both movements are desirable to be synchronized. This problem appears in the waste collection in suburban areas of Brazilian cities, as in country cities, where a truck collects in a waste generator sector some streets continuously and a laborer perform a walking tour collecting and joining waste in special points where the vehicle will pass. We present the problem as a multi-objective combinatorial optimization problem, propose a procedure to solve it, and evaluate solutions considering what is doing in the field, what can be planned without algorithm support, and finally with algorithm support for the sectors of the cities of Andrada, Jales and São José do Rio Pardo/São Paulo-Brazil.

Pricing Strategies

Stream: Pricing and Revenue Management
Invited session

Chair: Yeqing Zhou

1 - Optimal Pricing with Customer Heterogeneity in Duopoly Markets: Insights from Network Effects

Kimitoshi Sato, Nako Iwaji

This study considers a pricing problem in a duopoly market where customers have different preferences with respect to congestion. Customers choose a product based on the quality and price of the product sold by each firm, as well as the degree of congestion (aggregate demand) for that product. Customers who prefer congestion are more likely to choose a store if the store is more congested in order to obtain utility. Such a phenomenon is called a positive network effect (customer type P). On the other hand, customers who do not like congestion will use a store when it is less congested. This is called a negative network effect (customer type N). In this study, we formulate a price competition model under a linear demand function in order to clarify how the intensity of the network effect and the ratio of customer types affect competition among firms. Our analysis reveals that the equilibrium price increases with the number of type P, and the maximum revenue of both firms increases accordingly. The higher the intensity difference between positive and negative network effects, the higher the profit of the firm with good quality increases and that of the firm with poor quality decreases. Furthermore, comparing the case where both firms jointly determine prices and the competitive situation, we show that when the ratio of type N and the negative network effect are strong, the profit from competition exceeds that of joint.

2 - Optimizing Monopoly Airline Markets: An Integrated Approach to Scheduling, Fleet Management, and Dynamic Pricing

Soheil Sibdari

This study introduces a sophisticated model designed to optimize operational efficiency and revenue management for airlines operating within monopolized markets. Unlike previous models that separately address scheduling, fleet assignment, and pricing strategies, our approach integrates these components into a unified framework. The model leverages advanced algorithms to simultaneously determine optimal flight schedules, fleet allocation, and pricing strategies, taking into account demand elasticity, competitive dynamics, and operational constraints. We incorporate real-time data analytics to dynamically adjust the model parameters, ensuring the airline's ability to respond to market fluctuations and passenger preferences effectively.

3 - Empirical and Theoretical Results on Bertrand Duopoly with Interaction

Arik Sadeh

The Bertrand competition is an arena where firms compete in the price market. In Cournot games, firms compete by setting their quantities in the market. The attractiveness of Bertrand's games in economics is the visibility of prices to all competitors. Games are commonly used in markets with a few decision makers where the playing firms see downward demand functions. In this study, we analyze two firms in a duopoly market. The firms sell nonidentical products that satisfy the same customers' needs. The demand function for each firm is based on its price and the competitor's price, along with an interaction of both prices on each demand. We show that there is more than one Nash equilibrium point that leads to stability questions, The role of the cost function, its functional form, and parameters impact the number of potential equilibrium points. This is an essential issue in markets with technological and innovative products. The dynamics of Bertrand's games can serve as a mechanism to reveal the costs of the competition. Along with the optimal paths for the players under varying circumstances, we developed a simulator to handle various scenarios relevant to research.

4 - Simple Policies for Joint Pricing and Inventory Management

Yeqing Zhou, Adam Elmachtoub, Harsh Sheth

We study the fundamental joint pricing and inventory control problem, where the customers are price sensitive. In the continuous review infinite horizon setting, the optimal policy is known to be an (s, S, p) policy, and the optimal price changes for every inventory state. We consider policies with only a small number of prices offered and compare these policies to the optimal policy. When customer valuations follow an MHR distribution, we provide policies with theoretical guarantees for revenue and costs. In the lost sales case, we show that there exists a single price policy that achieves at least as much revenue as the optimal dynamic policy while incurring costs at most $\sqrt{1+\ln S}$ times more. The cost ratio is improved to 1.225 when the valuation distribution is uniform. When backlogging is allowed, we show that a three-price policy can achieve similar guarantees.

Advanced heuristics for machine scheduling

Stream: Project Management and Scheduling
Invited session

Chair: Léa Blaise

1 - Flight test scheduling: An integer programming model and a large neighborhood search algorithm

Guopeng Song, Hanqiao Tao, Roel Leus

Flight tests play a critical role in the research and development of new aircraft as they help verify the airworthiness and capabilities and expose design and manufacturing defects. During the test course, a large number of test tasks need to be scheduled appropriately so that the flight tests can be completed with minimum cost and high efficiency. Therefore, there is a strong need for developing an efficient method that can generate high-quality test schedules. In this paper, we study the flight test scheduling problem to minimize the number of required test flights, thereby decreasing the cost and time required during the entire test course. We establish a mixed-integer programming model to formally describe the problem, propose several computationally efficient lower bounds to help verify the quality of obtained solutions, and develop a large neighborhood search algorithm for generating a high-quality solution of the flight test scheduling problem effectively. Comprehensive computational experiments are performed to demonstrate the efficiency of our proposed algorithm. We report some general managerial insights based on the obtained computational results.

2 - More powerful energetic reasoning using redundant resources for the Cumulative Scheduling Problems

Kristina Kumbria, Jacques Carlier, Antoine Jouget, Abderrahim Sahli

In this presentation, we are dealing with the Cumulative Scheduling Problems (CuSP). In the CuSP-decision, we are given a set I of n non-preemptive tasks, meaning that once a task begins execution, it cannot be interrupted until completion. A constant amount m of a given resource is available over the time horizon to process the tasks. Each task i has a release date r_i , a processing time p_i , and a deadline d_i . The task i must be executed within its time window $[r_i, d_i]$, and throughout its execution it requires a constant known amount c_i of resources. The objective of this decision problem is to detect infeasibility. Until now, for this problem, the most efficient algorithm is based on energy reasoning. We have already proposed a more powerful energetic reasoning by solving a tripartition problem and built a checker by using a Dynamic Programming method. In the CuSP-optimization, the deadline d_i is replaced by the tail q_i which is equal to $C_{\max} - d_i$ and the objective is to find the minimal makespan C_{\max} . The energetic

lower bound corresponds to the minimal value for which infeasibility may not be detected. We can solve this problem by using the checker already proposed for the CuSP-decision. We also improved the efficiency of the method by introducing redundant resources. Computation results confirm the efficiency of the proposed methods.

3 - Scheduling in Offshore Wind: Developing a Simulation Tool Representative of Stochastic Weather

Hans Schwartzlose, Kong You Liow

Scheduling of activities and resources occurs across various sectors, especially those susceptible by uncertainty, where budgets are significantly impacted by delays, and a need for sudden reprioritization. At Ørsted Wind Power operations, we face challenges due to weather conditions that affect accessibility of wind farms for multiple types of operation & maintenance. To address these challenges, we have created a Scheduling Engine designed to integrate weather uncertainties into our planning systems. We are aiming to deploy the engine to planning problems ranging from tactical asset planning over major component exchange campaign planning, to operational weekly planning. Embedding the engine into our planning systems enables the creation of multiple scenarios and assists in understanding the potential impacts of weather conditions durations. Building upon its generic foundation, with the capability of custom adaptation to the specific scheduling problem, we aim to extend the Scheduling Engine to become the go-to tool for all planning and scheduling needs within Ørsted Wind Power Operations. This presentation outlines some of the complexities in designing the generic scheduling engine and developing it for real-world application.

4 - Disjunctive scheduling using interval decision variables with Hexaly Optimizer

Léa Blaise

Hexaly Optimizer, formerly known as LocalSolver, is a "model and run" mathematical optimization solver based on various exact and heuristic methods. The presentation will introduce the different components of Hexaly Optimizer's local search through disjunctive scheduling problems. We will first show how its modeling formalism can be used to express various academic and industrial scheduling problems using interval and list decision variables. These models are very compact, which enables the solver to handle even large-scale problems. Detecting non-overlap constraints in the model provides the solver with valuable information, which can be exploited through various scheduling-specific movements implemented in Hexaly Optimizer's local search. However, due to the tightness of precedence and non-overlap constraints in good solutions to disjunctive scheduling problems (Job Shop Scheduling Problem, for example), such a small-neighborhood search alone struggles to obtain good performance. Hexaly Optimizer overcomes this issue by reinforcing its local search component with a solution repair algorithm based on constraint propagation. When a move renders the solution infeasible, it is gradually repaired, one constraint at a time, by heuristically shifting the variables just enough to repair. To extend the local transformation rather than cancel it, and to ensure the procedure is fast, we impose never to backtrack on a previous decision to increase or decrease a variable's value.

Serena Fugaro, Antonino Sgalambro

Facility Location problems have been studied intensively due to their wide range of practical applications in various sectors such as Humanitarian Aid Logistics, Healthcare, Public Transport. In general, the decisions involved in Facility Location are inherently strategic, leading to the definition of problems characterised by many, potentially conflicting, objectives. The literature on Multi-Objective Facility Location problems is extensive and growing rapidly, yet there is a lack of contributions that comprehensively illustrate the state of the art. For this purpose, we conducted a thorough systematic literature review by analysing a sample of 193 relevant papers published in international peer-reviewed journals between 2011 and 2023. Indeed, we focused on modelling and algorithmic aspects, as well as on the managerial context underlying the arising problems and yielding to their inherent Multi-Objective nature. This study has identified several research gaps at the modelling and methodological level, but also in terms of prominent potential applications not addressed so far from a managerial and practical perspective. Accordingly, we present some findings from our analysis and propose a research agenda outlining some future research directions in Multi-Objective Facility Location for both researchers and practitioners, and signposting how theoretical advancements could enable provision of services and design of systems that are more inclusive, resilient and robust.

2 - Extensions to Competitive Facility Location with Multi-purpose Trips

Malgorzata Miklas-Kalczynska

Competitive facility location models involve locating one or more new facilities on the market where competing facilities already exist. The goal is for the added facilities to capture the maximum possible market share. Recent extensions to the classic competitive facility location problem introduce multi-purpose shopping for complementary or substitute goods. The idea comes from the observation that customers often shop for different goods and visit multiple locations during a single trip. The facilities (called clusters) offering these other goods exist but do not compete with our chain. The multi-purpose, multi-stop models existing in the literature thus far are, in fact, two-purpose, which means that they assume a customer makes either a single stop or two stops before returning to the point of origin.

We formulate an extension to a two-purpose continuous competitive facility location model, introducing the possibility of more than two stops when shopping for complementary goods or services. Our problem is non-linear and non-convex, thus difficult to solve. We provide a solution technique and run experiments on instances incorporating 100 to 20,000 demand points and up to 20 facilities. We compare the solutions obtained by our model to the single-purpose and the two-purpose models. We show that introducing the possibility of more than two stops increases the market share captured by our chain.

3 - A bilevel gradual covering facility location model with customer preferences and different facility types

Hande Kucukaydin

We address a gradual covering competitive facility location problem where two competing retailers must decide on opening various types of facilities by taking into account customer preferences represented by probabilities for visiting different facility types. It is assumed that customers at a demand point are entirely willing to travel to a specific type of facility when it is located within a full coverage radius. However, if a facility is positioned beyond this full coverage distance, customers are either partially covered or not covered at all. It is also assumed that customers at a demand point can visit several facilities of different types of a retailer. However, among facilities of the same type, customers at a demand point can visit more than one facility of the same type if each facility belongs to a different retailer's chain. In such a case, the captured proportion of the buying power by a single facility is determined by both its own coverage extent and the total coverage provided by all facilities, which may lead to a loss of some buying power. Thus, the revenue generated by a facility depends not only on the visiting probabilities but also on the coverage strength in the presence of competitors. We formulate a nonlinear integer bilevel programming model and propose tabu search heuristics for the solution.

Location with Multiple Actors

Stream: Locational Analysis

Invited session

Chair: Boglárka G.-Tóth

1 - A systematic literature review and research agenda on Multi-Objective Facility Location

4 - A Stackelberg location problem on the plane using delivered price equilibria

Boglárka G.-Tóth, Jose Fernandez

We study the problem of finding the optimal location and price equilibria of a Stackelberg location game when price equilibria are used. First, the leader and then the follower choose their locations and then set delivered prices to maximise their profits. Previous work has solved problems of location-price equilibria on different settings, showing that the minimiser of the social cost gives a location equilibrium. Any solution to the Stackelberg problem is also a location equilibrium, and it can be shown that there are location equilibria which are not minimizers of the social cost. Our research question is whether there may exist a Stackelberg solution which is not an equilibrium provided by the social cost. Assuming that firms set the equilibrium prices after the locations are fixed, the problem can be modelled as a bilevel optimization problem. We propose an exact interval branch-and-bound algorithm, suitable for relatively small problems, to obtain rigorous solutions. Our main goal is to see how the Stackelberg solution can differ from the location-price equilibria provided by the minimization of the social cost.

Container Stacking and Yard Planning II

Stream: OR in Port Operations

Invited session

Chair: *Christopher Expósito Izquierdo*

1 - Container relocation and retrieval tradeoffs minimizing schedule deviations and relocations

Robert Klar, Anders Andersson, Anna Fredriksson, Vangelis Angelakis

Ports are striving to improve operational efficiency in the face of ever-increasing trade volumes. In this context, the operation of port terminal storage yards is key, as complexity and poor coordination lead to containers being stacked without regard to retrieval schedules, resulting in time- and energy-consuming reshuffling operations. This problem, known as the block relocation (and retrieval) problem (BRP), has recently received considerable attention. While there are promising solutions to the BRP, the literature considers the problem in isolation, optimizing a single operational parameter for one of the many port stakeholders. This often leads to efficiency losses, since port processes involve different stakeholders and port parts. In this work, we explicitly focus on the scheduling of trucks for hinterland distribution: schedules are often shifted to minimize reshuffling, which causes losses to transport forwarders and reduces the competitiveness of the port. We discuss the trade-off between minimizing the number of container reshuffles and minimizing the deviation from the scheduled time windows for container retrieval by introducing a multi-objective optimization problem. Given the complexity of the problem, we present a greedy heuristic. Our results indicate that the number of schedule deviations can be reduced without significantly affecting the number of relocations.

2 - Container Space Allocation using a Dominance-Based Rough Set Approach (DRSA)

Jana Ries, Salem Chakhar, Rosa G. González-Ramírez

Considering growing number of TEUs shipped globally, there continue to be increasing resource constraints in container ports. In addition, changing and uncertain exogenous factors impact predictability and efficiency of container port operational planning. A DRSA approach is introduced, integrating a multi-criteria classification problem into the solving approach of the container space allocation problem. The approach is discussed in the wider context of port operations, emphasising the sensitivity of the problem solution on operational planning strategies within a port system.

3 - Iterated Greedy for the Yard Crane Scheduling Problem

Hongtao Wang, Rubén Ruiz, Eva Vallada, Fulgencia Villa

Yard crane scheduling problems (YCSPs) arrange requests for loading containers by yard cranes on terminals. Of the scheduling nature and operational complexity is a real-world YCSP with the assignments of input/output (I/O) points that serve as dynamic buffers to receive and send containers. The YCSP schedules storage and retrieval containers coordinated with their time parameters at the I/O points, which are also limited and need to be assigned during the scheduling process. Instead of proposing hybrid or complicated approaches, we introduce a series of simple Iterated Greedy (IG) methods upon a classical vanilla IG. New destruction, reconstruction and local search operators are designed for task schedules and I/O assignments. It results in 3 IG algorithms which require little variation from the vanilla IG. Extensive computational campaigns have shown a statistically wide margin of the proposed IG methods over several state of the art approaches.

Advanced Options Strategies Using O.R. and Machine Learning

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: *Ilkay Boduroglu*

1 - A Machine Learning Model for Options Traders that Predicts the Magnitude but not the Direction of Post-Earnings Stock Price Jumps

Ilkay Boduroglu

US companies typically announce their earnings report after the stock market has closed. Their stock price usually experiences a significant move, up or down, the following day. Predicting the direction of this movement can be tricky, as the stock price may go down even after a good earnings report and vice versa.

As a result, market players focus on non-directional options strategies, such as Iron Condors, to capture a quick profit overnight. Even then, if the magnitude of the post-earnings price move (in either direction) is too large, this strategy ends up losing money. Therefore, it is crucial to predict the magnitude of the post-earnings price change successfully. A highly successful predictive model could make a massive difference in a hedge fund's performance.

This paper aims to develop a Machine Learning model that predicts the magnitude of the post-earnings stock price change. We first noticed that Estimote.com is an acclaimed data provider in the finance industry, and it publishes consensus predictions for earnings reports based on the predictions of its best competing analysts. Also, Thomson Reuters, one of the two major data providers in finance, publishes Estimote's consensus predictions the day before earnings releases. We then decided to record the variance of the most confident analysts' predictions at Estimote. We then analyzed the relationship between this variance and the magnitude of the post-earnings stock price change. We have promising results.

2 - Creating Optimal Speculative Portfolios for 0-DTE (Zero-Days-To-Expire) SPY Options

Yusufcan Ozkan, Ilkay Boduroglu

The daily notional volume of 0-DTE SPY options is over 1 billion USD. We created an Integer LP model to take advantage of this market every day. Our out-of-sample backtests produce Sharpe ratios that exceed 3. We include commissions, slippage, and the margin requirement, without which the results would have been unrealistic.

Our model, similar to Papahristodoulou's (2003), is formulated so that the model's optimal solution will determine the optimal speculative portfolio. The integer decision variables are the quantities of available 1-DTE SPY options contracts. We assume we can trade these quantities a very short time before the closing bell, the day before the expiration date. So, technically, we trade 0-DTE SPY options contracts. In the future, we shall experiment with SPX options, which are cash-settled, unlike SPY options.

We use constraints that limit all significant portfolio Greeks, delta, gamma, theta, rho, and vega. Since there is only one underlying instrument, SPY, and one specific expiration date, all Greeks are additive in each portfolio. Our objective function maximizes the sum of differences between theoretical prices and market prices of available options, net of commissions and slippage. We compute theoretical prices as in Papahristodoulou (2003). The gist of our paper is the way we calculate the theoretical prices of options and the validity of this computation.

3 - Deep learning-based allocation for financial strategy replication in incomplete market.

Johan Macq, Yannick Malevergne, Marc Sennneret, Patrice Abry

We develop and implement a model-free, deep learning-based approach to tracking the performance of a chosen financial strategy in the presence of market frictions. Our method provides the optimal dynamic allocation over a - possibly time-varying - set of trading instruments. To achieve the optimal replication strategy, we introduce a novel architecture called Universal Allocators, inspired by Transformer networks. Its number of parameters is independent of the dimension of the investment universe and the length of the training path, allowing it to handle large portfolios without additional computational cost. We implement an adversarial training scheme using the Wasserstein-1 distance to solve the replication task. To the best of our knowledge, this is the first time that an adversarial training scheme using the Wasserstein-1 distance has been used to solve such a problem. To illustrate our method, we replicate a highly non-linear strategy, similar to a collar index, which provides the daily performance of an underlying asset whose values have been clipped below and above a given threshold. The replication set consists of a large number of vanilla options whose strike prices and expiration dates are defined over a discrete and sparse lattice, making the market incomplete. Using both simulated and S&P500 data, we show that our method provides financially meaningful and interpretable allocations for replicating such a strategy at moderate cost.

4 - Portfolio Optimization and Parameter Uncertainty

Anton Vorobets

Portfolio optimization has a mixed reputation among investment managers, with some being so skeptical that they believe it is almost useless due to the inherent parameter uncertainty. It is undeniable that portfolio optimization problems are sensitive to parameter estimates, especially the expected returns that are arguably also the hardest parameters to estimate. However, most practitioners still attempt to build mean-risk optimal portfolios, albeit in implicit ways. Resampled optimization is a popular mathematical heuristic to tackle the parameter uncertainty issue. It computes optimal portfolios using sampled parameter estimates and calculates a simple average of the portfolio exposures across samples. The unsatisfactory aspect of the resampled approach is that there is no mathematical justification for using the average of portfolio exposures, it just works well in practice. This article provides perspectives for understanding the resampling approach by analyzing the portfolio exposure estimation process from a bias-variance trade-off. We show that the traditional resampled optimization corresponds to a naive version of stacked generalization. Finally, we introduce a stacked generalization approach that can be used to handle both parameter uncertainty and combine optimization methods in full generality. We coin the new method Exposure Stacking.

Tuesday, 12:30-14:00 - Room: S16 (building: 101)

Dynamic Vehicle Routing 1

*Stream: VeRoLog - Vehicle Routing and Logistics
Invited session*

Chair: Karl Doerner

1 - Dynamic Routing and Scheduling Optimization of Teleoperated Car-Sharing Service

Gideon Gottschalg, Arne Strauss, Marlin Wolf Ulmer, Jarmo Haferkamp

Teleoperated vehicles are a promising concept for increasing the attractiveness and profitability of car-sharing services. Such vehicles can be remotely steered by an operator to the location of an on-demand vehicle requesting user. It eliminates the need for users to walk to a car-sharing vehicle and the need for providers to relocate vehicles with drivers on site to meet the temporal and spatial vehicle demand. To ensure an acceptable service level, an effective utilization of the vehicle fleet and the number of operators is required. The decision process involves deciding which vehicle should be steered next by which operator to fulfil which user request. This is challenging as the future demand and the future availability of vehicles are uncertain, since the rental duration and return location are unknown. We tackle this problem with a two-step allocation algorithm that combines a cost function approximation with the prediction of future vehicle returns to minimize the waiting time for current and potential future users. The first step identifies effective vehicle-user matchings which balance waiting times and driving efforts. In the second step, the sequence of identified matchings to be executed by the operators is determined, anticipating potential improvements by predicted future vehicle returns. We demonstrate the merits of our approach in comparison to intuitive benchmark policies in a computational study highlighting the characteristics of this novel problem.

2 - A Rollout Algorithm for Dynamic Stochastic Purchasing Routing With Perfect Information Model Estimation

Daniel Cuellar-Usaquen, David Álvarez-Martínez, Marlin Wolf Ulmer, Camilo Gomez

This paper addresses the dynamic stochastic purchasing routing problem faced by a purchaser in negotiating with multiple suppliers to meet its demand. The purchaser contacts suppliers sequentially and must decide whether to buy based on purchase prices, available quantities, and routing costs. Each supplier can be contacted only once, with uncertain price and quantity information revealed upon contact. The purchaser faces a maximum number of contacts within a planning horizon. This problem is challenging because of the dynamic stochastic components of the negotiation process. The purchaser must weigh the information revealed by the current supplier against the remaining suppliers' behaviors and route consolidation to make decisions. We propose a rollout algorithm that combines dynamic programming with a perfect information model to determine whether to purchase from the current supplier and which supplier to contact next. Our method samples the supplier behavior scenarios and solves independent deterministic problems to estimate the opportunity cost of not purchasing from remaining suppliers or the impact of purchasing from the current supplier. We introduce a reverse discount factor to reduce the optimism in perfect information model estimation. Our method is validated against benchmark policies using real procurement data from an e-commerce platform. Results confirm the superior performance of the rollout algorithm and provide insights into benchmark policy effectiveness.

3 - The On-Demand Delivery Problem: Online Assignment of Orders to Warehouses and Couriers

Peter Dieter, Philipp Speckenmeyer, Guido Schryen

The surge in customers' preference for online shopping has spurred the growth of on-demand delivery services, exemplified by companies like Getir, Gorillas, and Flink. These companies promise near-instantaneous deliveries, typically within a few minutes. To be able

to fulfill this promise, multiple micro-warehouses and a courier fleet using e-bikes are employed. To address the assignment problem, the current practice of logistics companies is to statically define spatial areas as polygons for each micro-warehouse and assign all customers within this polygon to the respective warehouse. However, such a static assignment neglects real-time information that might be used to achieve a better workload balance of orders between warehouses. In this work, we suggest a dynamic and data-driven assignment of orders to warehouses and couriers based on the current workload and previously assigned orders to the warehouses. The problem is formalized as a sequential decision problem, as customers arrive dynamically over time. The goal is to minimize total tardiness. We develop methods to solve the considered problem and apply them to problem instances on a stylized grid as well as to instances derived from real-world data of Chicago. Our methods are benchmarked to current practices from the industry, showing that a dynamic assignment can substantially reduce tardiness.

1 - Optimizing machine learning: Enhancing interpretability and performance through mathematical optimization

Veronica Piccialli

This presentation highlights the interplay between optimization and machine learning, examining two pivotal examples. First, we will explore how mathematical optimization can significantly enhance the interpretability of machine learning models, with a focus on classification problems. Interpretability is a crucial requirement for the practical deployment of machine learning models across diverse fields. Optimal decision trees are fundamental tools for building robust and interpretable classification models. However, the challenge lies in their inability to ensure optimality for large datasets. Recently some efficient approaches have been introduced for building optimal decision trees that require all the features to be binary. We will describe an efficient optimization-based approach for deriving a supervised discretization of the original dataset. Thanks to the use of optimization, the proposed technique allows to control the importance of the features extracted, and hence the granularity of the discretization. This novel technique not only facilitates the training of a robust and interpretable optimal decision tree but also allows to address the complexities associated with larger datasets. Finally, we'll transition to a pragmatic application in process engineering, showcasing the successful integration of optimization and machine learning to solve an important real-world problem.

1 - Modelling and pricing of multi-region catastrophe bonds

Krzysztof Burnecki

The insurance-linked securities (ILS) market, as a form of alternative risk transfer, has been at the forefront of innovative risk-transfer solutions. The catastrophe bond (CAT bond) market now stands for almost half of the whole ILS market and is steadily growing. Since CAT bonds are often tied to risks in different regions, we follow this idea by constructing different pricing models that incorporate various scenarios of dependence between catastrophe losses in different areas. Namely, we consider independent, proportional, and arbitrary two dimensional distributions cases. We also derive normal approximations of the prices and compare them with prices obtained via bootstrapping. We find significant difference between those approaches. We believe that these findings can be helpful in modelling and pricing of other ILS tied to natural disasters. For illustration purposes we analyse Property Claim Services data.

2 - Ruin probability of the insurer-reinsurer quota-share model with phase-type distributed claims

Marek Teuerle

In this work, we consider a bivariate risk process describing the capitals over time of two insurance companies that share premiums and claims with fixed proportion. Such a model can be used in modeling of the capital for the insurer-reinsurer system with proportional reinsurance [1-5]. Our main results include a formula for the ruin probability of insurer or reinsurer in the infinite time for phase-type distributed claims [5]. Additionally, we will introduce two alternative methods for approximating the aforementioned ruin probability: De Vylder-type and diffusion approximations [2,4]. The accuracy of our results is validated using both synthetic and empirical data [2-5].

3 - Explainable AI methods for early warning system of financial crisis prediction

Jurgita Cerneviciene, Audrius Kabasinskas

Accurately predicting financial crises holds immense significance for the national economy and the financial sector. The market's instability has significant implications for decision-making processes, emphasizing the need to accurately predict and anticipate economic fluctuations at the earliest possible stage. Early warning methods can be a valuable tool for financial risk managers in reducing the likelihood of extreme losses. With the advent of modern technology and the availability of real-time data, it has become feasible to create forecasting models that can provide almost instantaneous predictions of financial crises. In this study, we present a technique that combines Artificial Neural Network, Random Forest, and XGBoost to analyze and predict the possibility of a financial crisis based on various performance indicators of pension funds, such as return on investment, risk level, and other related ratios. By employing the rolling window technique and methods of Explainable Artificial Intelligence (XAI), such as SHAP (Shapley Additive explanations) and LIME (Local Interpretable Model-agnostic Explanations), a comprehensive analysis was conducted. According to our results hidden market regime (forthcoming financial crisis) within one to ten days can be predicted with a high degree of accuracy. The risk-adjusted performance metrics, such as the Bernardo and Ledoit ratio, Sterling Ratio, Sortino ratio, and Pain index, turnout to be the most important measures.

4 - Modelling shock propagation and resilience in financial temporal networks

Giorgio Rizzini, Fabrizio Lillo

We provide a model for shock propagation and resilience in a temporal network. Each node is a bank and two banks are connected through an arc if a bank lends money at least once to another bank in a period. We assume that each node is associated with two latent parameters, i.e. the fitnesses, describing its propensity to create incoming and outgoing links at any time. At each time, the presence of an arc in the network is an independent realization of a Bernoulli random variable with probability specified by a link function of the fitness of two nodes. We assume that the fitness vector evolves accordingly to a VAR(1) through which it is possible to model the lagged interactions between fitness. In this framework, our aim is to study the resilience of a temporal network by proposing a modification of the impulse response analysis, which, in the network case, is a non-linear function of the shock intensity. We study on how a shock on a node of a temporal network propagates and how the system relaxes back to the equilibrium state. We also propose

a novel econometric estimation model that combines the Maximum Likelihood Estimation method and the Kalman filter to estimate the fitness dynamics. We test our methodology to synthetic networks and then we apply it to the electronic Market of Interbank Deposit network. The analysis is suitable to detect evolutionary features and the relationships among financial institutions highlighting which are the critical banks in shock spreading

1 - Provably convergent algorithm for free-support Wasserstein barycenter of continuous non-parametric measures

Qikun Xiang, Zeyi Chen, Ariel Neufeld

We propose a provably convergent algorithm for approximating Wasserstein barycenter of continuous and non-parametric measures. Our algorithm is inspired by the fixed-point scheme of Álvarez-Esteban, del Barrio, Cuesta-Albertos, and Matrán (2016), which begins with an initial measure and iteratively updates it via its pushforward by the mean of optimal transport (OT) maps to the input measures. However, the convergence of their scheme relies on obtaining exact OT maps which is computationally intractable for general non-parametric measures. Hence, we develop consistent estimators of OT maps via shape-constrained least squares regression, and replace the OT maps in the fixed-point scheme with their estimated counterparts. This gives rise to a stochastic fixed-point algorithm which is provably convergent to the true barycenter. Specifically, in order to obtain consistent OT map estimators, we develop tailored approximation techniques for preserving the regularity of both the true OT maps and the estimated OT maps throughout the iterations. Moreover, our algorithm does not restrict the support of the barycenter and can be implemented in a distributed computing environment. These properties make it suitable for large-scale information aggregation problems, e.g., multi-expert consensus in recommender systems and distributed sensor networks. In our numerical experiment, we showcase the practicality and efficiency of our algorithm for expert consensus on probabilistic forecasting.

2 - A Novel Criterion for Batch Size Adaptation in Stochastic Gradient Methods

Marco Boresta, Alberto De Santis, Stefano Lucidi

In this work, we introduce a novel interpretation of the variance associated with batch gradient estimates in machine learning model training. By reevaluating this variance, we introduce a novel strategy for the dynamic adjustment of batch sizes throughout the training process. This approach diverges from traditional approaches by prioritizing a more detailed representation of variance behavior, which can lead to more efficient and effective training regimes. We test our methodology against a series of problems, benchmarking it against current state-of-the-art methods to demonstrate its advantages and applicability.

3 - Data-Driven Submodular Set-function Optimization: Theory and Applications in Assortment Planning and Recommender Systems

Jigar Patel

Recommender systems and informed assortment planning facilitate the display of goods or services tailored to individual customer needs/characteristics, promote the visibility of assorted products, and revenue growth. We address the problem of optimal assortment and display of online search results for goods or services. The objective is to maximize the platform's revenue and customer engagement by leveraging the menu of displayed search results to users, subject to

catering to their individual search criteria or characteristics. Our analysis is based on a detailed data set from a leading online platform. Assortment planning involves optimization over a utility set-function. For example, a supermodular utility function is related to complementary goods, and a submodular utility function is related to substitutes. By analyzing our data, we identify properties of our utility function and implement the proper optimization algorithm tailored to individual users. Recent advances in the discrete optimization field has enabled us to provide optimal or near-optimal algorithms in polynomial time to tackle the difficult problem of submodular function optimization

Robust and Multi-Level Optimization

Stream: MINLP

Invited session

Chair: Maximilian Merkert

1 - On the Complexity of the Bilevel Shortest Path Problem

Dorothee Henke, Lasse Wulf

We introduce a new bilevel version of the classical shortest path problem and completely characterize its computational complexity with respect to several problem variants. In our problem, the leader and the follower each control a subset of the edges of a graph and together aim at building a path between two given vertices, while each of the two players minimizes the length of the resulting path according to their own edge lengths. We investigate both directed and undirected graphs, as well as the special case of acyclic directed graphs. Moreover, we distinguish two versions of the follower's problem: Either he has to complete the edge set selected by the leader such that the joint solution is exactly a path, without any additional edges, or he is allowed to include only a subset of the leader's selection into the final path. In general, the bilevel problem turns out to be much harder in the former case: We show that the follower's problem is already NP-hard here and the leader's problem is even hard for the second level of the polynomial hierarchy, while both problems are one level easier in the latter case. Interestingly, for acyclic directed graphs, this difference turns around, as we give a polynomial-time algorithm for the first version of the bilevel problem, but it stays NP-hard in the second case.

2 - Robust Optimization Under Controllable Uncertainty

Eva Ley, Rebecca Marx, Maximilian Merkert, Tim Niemann, Sebastian Stiller

Applications for optimization with uncertain data in practice often feature a possibility to reduce the uncertainty at a given query cost, e.g., by conducting measurements, surveys, or paying a third party in advance to limit the deviations. To model this type of applications, we introduce the concept of optimization problems under controllable uncertainty (OCU). For an OCU we assume the uncertain cost parameters to lie in bounded, closed intervals. The optimizer can shrink each of these intervals around a certain value called hedging point, possibly reducing it to a single point. Depending on whether the hedging points are known in advance or not, different types of OCU arise. Moreover, the models may differ with respect to when the narrowing down, the underlying optimization, and/or the revelation of true data take place. In the talk, we discuss two example problem settings - one with known and one with unknown hedging points - in more detail, where we handle the remaining uncertainty by the paradigm of robust optimization. For both cases, we give conditions under which a single-level reformulation is possible. Throughout the talk, we use shortest-path problems as underlying optimization problem for illustrating specifics of and phenomena arising in OCU.

3 - A large and natural Class of Sigma-2- and Sigma-3-complete Problems in Bilevel and Robust Optimization

Lasse Wulf

Because Sigma-2- and Sigma-3-hardness proofs are usually tedious and difficult, not so many complete problems for these classes are known. This is especially true in the areas of robust and bilevel optimization (we focus in this talk on min-max-regret, interdiction, most vital vertex, and two-stage robust optimization problems). Even though these areas are well-researched for over two decades and one would naturally expect many (if not most) of the problems occurring in these areas to be complete for the above classes, almost no completeness results exist in the literature. We address this lack of knowledge by introducing over 70 new Sigma-2-complete and Sigma-3-complete problems. We achieve this result by proving a new meta-theorem. This meta-theorem applies to most classical problems, like clique, vertex cover, knapsack, TSP, facility location and many more. In summary, our work reveals the interesting insight that a large amount of NP-complete problems have the property that their min-max versions are 'automatically' Sigma-2-complete.

4 - A Branch-and-Bound Scheme for a Class of Partial Inverse Combinatorial Optimization Problems

Maximilian Merkert, Eva Ley

We consider partial inverse optimization problems, which are bilevel optimization problems in which the leader aims to incentivize the follower to include a given set of elements in the solution of their combinatorial problem. For solving partial inverse combinatorial optimization problems with only weight increases, we present a new branch-and-bound scheme. In this talk, we focus on the partial inverse shortest path problem with only weight increases. Branching on follower variables, the scheme relies on two different methods that are basically complete inverse shortest path problems on similar graphs, which are known to be solvable in polynomial time. Computational experiments suggest that for dense graphs our branch-and-bound scheme outperforms an MPCC reformulation as well as a decomposition scheme.

1 - A methodology of predict-interpret-suggest for used car pricing

Qihao Wu, Yong-Hong Kuo

Pricing used cars is a complicated process that involves various influencing factors. This study deploys a series of interpretable machine learning models to predict used car prices with elaborate feature engineering. A comparative analysis reveals that ensemble tree algorithms can achieve the highest performance, with an R-squared value exceeding 0.93. Through examining the interpretable feature attributes, the used cars' age, make, and engine capacity are ranked as the top three most significant determinants of price. Furthermore, our wrapper method explores the heterogeneity of features and datasets, by which the performance of neural networks with numerical features on more specific data is highlighted. Finally, the treatment effects of significant binary variables are summarized as suggestions for consumers. By integrating predictive modeling, interpretability, and causal inference, this study presents a novel Predict-Interpret-Suggest framework for the used car market.

2 - A network-based model for dynamic analysis of the banking sector

Riccardo Bastianutti

This paper introduces an innovative model to interpret the dynamics of banking sector, moving away from the traditional reliance on individual firm variables. Instead, it proposes a network approach to capture information from inter-firm interactions. The model utilizes Principal Component Analysis (PCA) to extract the first principal component, interpreted as a proxy for each firm's weight within the banking sector. A graph is constructed, with the first principal component acting as the weight for links between firms, and the firm with the highest weight serving as the network's center. Applied to a dataset of banking sector firms, the model effectively captures sector dynamics. Active nodes, those with an indegree greater than zero, are identified and analyzed over time. Results are compared with the S&P 500 index, revealing a strong correlation (above 0.91). Additionally, a predictive model is implemented on the probability density function (PDF) of the first principal component to analyze sector evolution. Predictive models demonstrate an error of less than 5%, highlighting the model's robustness. The proposed model boasts several advantages over existing approaches. Firstly, it provides a more comprehensive view of the banking sector by considering inter-firm interactions. Secondly, it identifies key players in the banking sector and their impact on dynamics. Lastly, it offers predictive capabilities for the banking sector's future evolution.

3 - Source Condition Double Robust Inference on Functionals of Inverse Problems

Nathan Kallus

We consider estimation of parameters defined as linear functionals of solutions to linear inverse problems. Any such parameter admits a doubly robust representation that depends on the solution to a dual linear inverse problem, where the dual solution can be thought as a generalization of the inverse propensity function. We provide the first source condition double robust inference method that ensures asymptotic normality around the parameter of interest as long as either the primal or the dual inverse problem is sufficiently well-posed, without knowledge of which inverse problem is the more well-posed one. Our result is enabled by guarantees for novel iterated Tikhonov regularized adversarial minimax estimators based on minimax (robust) optimization over general hypothesis spaces.

Behaviour and decision support

Stream: Behavioural OR

Invited session

Chair: *Ilkka Leppanen*

1 - Do people willfully ignore decision support? Evidence from an online experiment

Stefan Haeussler, Sebastian Bachler, Katharina Momsen, Matthias Stefan

The increasing usage of decision support systems typically hinges on the assumption that objective information provision can improve decision-making. This premise, however, disregards the potential for humans to deliberately ignore information in a manner that serves their own interests. We study willful information avoidance in the usage of decision support with the help of an online experiment where participants solve a task of high cognitive complexity, i.e. a knapsack problem. We indeed find first evidence for motivated reasoning in our experiment in one of two dimensions: First, we do not find evidence that participants willfully ignore decision support when it might suggest revising their initial choices. Yet, we find evidence that they willfully

ignore information that might tempt them to act selfishly. Thus, participants use decision support to self-commit to more pro-social choices. Contrary to that, participants do not avoid decision support information to behave egoistically while maintaining a positive self-image. Although our results seem like good news, they show that even objective information provision in decision-support is no guarantee that humans acquire it in an unbiased way.

2 - Shaping Programmer Practices: Effective Strategies for Mitigating Bias in Machine Learning Algorithm Development

Seyedmohammadreza Shahsaheni, Osman Alp, Justin Weinhardt, Alireza Sabouri

In recent years, increased awareness of gender bias in machine learning has led developers to focus more on gender equality in model outcomes. This study investigates how fairness norms and accuracy thresholds impact developers' model choices and reporting decisions. The experiment design in this study replicates the machine learning algorithm development process. Results from 604 programmers participating in this experiment show that fairness norms led to the selection of fairer models (Hypothesis H1). Moreover, developers in companies valuing accuracy less prioritized fairness when informed of its norm (Hypothesis H2). Interestingly, we found that high accuracy thresholds with fairness norms encouraged participants to prioritize fairness, even at the expense of personal benefits. As an exploratory analysis, we study the reporting provided by programmers and the effect of their backgrounds and demographics on their models' performance. This study highlights the importance of fairness norms in guiding machine learning development and reporting, aiding gender equality in AI applications.

3 - Workload and Operational Performance in Digital Control Rooms: The Dual Role of Human-automation Interaction

Changyu Men, Marijn Verschelde, Maud Van den Broeke, Bart Roets

In today's business context, employees increasingly experience workload pressure, which impacts operational performance. To alleviate the workload burden and mitigate its potentially negative effects, automation is frequently seen as a solution. However, the mere implementation of automated systems is insufficient, and it is essential to understand employees' behavior in terms of how they interact with digital automation systems, a topic still understudied in current literature. Our study aims to expose the key role of human-automation interaction in relation to workload and consequential operational performance. For this purpose, we analyze a rich dataset of digital control rooms at a major European rail system operator. This unique and novel setting allows us to examine the impact of controllers' automation intervention willingness on their workload and operational performance. On the one hand, we find that a higher workload increases train delays and that employees who have a tendency to adjust the decision from the automation system experience a significant increase in workload. On the other hand, we find that employees with a tendency to adjust the automated system's decisions exhibit greater resilience to mitigate the negative effects of workload on train delays. These findings underscore the necessity to consider the dual effect of human-automation interaction in relation to workload management and operational performance and the value of studying new settings.

4 - Unveiling the credit nature of Buy-Now-Pay-Later

Mee Chi So

Consumers often see buy-now-pay-later (BNPL) as a convenient payment mechanism allowing them to spread the purchase cost over an interest-free period. Many consumers do not realise it is a form of credit and may result in late charges being incurred. This lack of understanding is one of the contributing factors that has led many BNPL users to overspend and accumulate debt. This project aims to transform our understanding of how BNPL impacts consumers' spending behaviour and inform information provision practices so that consumers can make better informed decisions. A series of experiments will be conducted to evaluate how BNPL should be presented so that

consumers are given appropriate and adequate information prior to investigating a contract. The results will inform financial regulators as they introduce regulation on BNPL offers, whilst helping protect consumers and ensure that BNPL is sustainable.

Long-term energy system planning

Stream: Energy Markets

Invited session

Chair: Kenneth Bruninx

1 - The role of CfDs in future Electricity Markets

Lena Kitzing

Against the backdrop of an ongoing debate on reforming the European electricity market, leading voices in academia and EU institutions agree that electricity markets must be supplemented with additional long-term options, including Contracts-for-Difference (CfDs). A key design question for renewable support schemes in general, and CfDs in particular, is how to prevent electricity market distortions and preserve short-term, operational market integration without jeopardising the effectiveness of the schemes in leveraging investment of private capital for renewable energy deployment. Different experts advocate for different versions and implementation options of CfDs, including generation-based and generation-independent design approaches. Generation-based two-sided CfDs have so far been used in more than 200 auctions across ten European countries, namely Denmark, France, Greece, Hungary, Ireland, Italy, Poland, Portugal, Spain, and the United Kingdom. We show that generation-based CfDs in existing designs can be non-distortive for day-ahead markets. Remaining issues arise through spill-over incentive effects across market segments (e.g. towards intraday, balancing and futures markets). We discuss generation-independent CfDs, which have theoretical advantages over generation-based designs, in particular in relation to intraday and balancing markets, but feature unresolved implementation challenges and would imply rather significant changes in the market.

2 - Capacity Expansion Planning under Uncertainty subject to EENS Constraints

Marilena Zambara, Daniel Avila, Anthony Papavasiliou

We present a method for solving a large-scale stochastic capacity expansion problem which explicitly considers reliability constraints, in particular constraints on expected energy not served (EENS). Our method tackles this problem by relaxing the EENS constraints. We solve the relaxed formulation in an iterative manner, using a subgradient-based method. Each iteration requires the solution of a stochastic capacity expansion problem, for which we implement subgradient and cutting plane decomposition schemes that have recently been introduced in the literature and have proven very effective in solving large instances of such models. We implement the proposed methodology on the Economic Viability Assessment (EVA) model that is used by ENTSO-e in the annual European Resource Adequacy Assessment (ERAA). The EVA is extended to include reliability constraints. We are able to solve this "extended" EVA and obtain the least-cost capacity expansion plan for meeting specific reliability requirements per zone, fully accounting for uncertainty. Our approach also allows us to attain the shadow price of load shedding by zone (through the Lagrangian multipliers of the relaxed constraints) which can serve as an indication of the zone-specific VOLL or price cap that could in principle deliver the appropriate level of investments within an energy-only market.

3 - Modeling long-term energy transition pathways: Algorithmic approaches and their properties

Stefan Strömer, Kenneth Bruninx, Stefan Pfenninger

Recently, challenges related to climate change have increased the need for ever more complex energy system models, covering more sectors, more technological detail, as well as high spatial and temporal resolution. Furthermore, step-wise decarbonisation goals (e.g., for the heat sector) may require contradictory system designs for different future years. Similarly, anticipated, but only slowly implemented, developments of the hydrogen system may necessitate certain transition technologies. With the inherent risks for lock-in effects or stranded assets, the timing of infrastructure investment decisions has increasingly gained importance. Current energy system models often focus either on designing this sector-coupled energy system in great detail, lacking knowledge of the pathway to achieve it, or on designing pathways to a decarbonised energy system, lacking a detailed consideration of the system's operation.

We give an overview of algorithms that help depict complex transition paths together with high operational details, e.g., adaptive temporal resolutions and ways to account for seasonal storage, classical decomposition algorithms (e.g., Benders), closely related algorithms such as stochastic dual dynamic programming (including extensions), as well as approaches based on simulation. We further discuss requirements and features, potential (dis)advantages, and present test cases to illustrate how these algorithms can be applied to a wide range of energy system models.

4 - A multi-objective optimization approach to assess the trade-off of potential energy and material supply risks in the energy transition

Gianvito Colucci, Valentin Bertsch, Valeria Di Cosmo, Jonas Finke, Laura Savoldi

This work proposes a methodology for the combined assessment of energy and material supply risks (SRs), using a multi-objective optimization (MOO) approach in energy system models (ESMs). Indeed, the transition from fossil fuels to low-carbon sources is decreasing the energy import dependency of many countries, while increasing the risk of potential bottlenecks along the entire supply chain of low-carbon technologies, leading to an energy security trade off. As policymakers are promoting new devoted policies, ESMs represent suitable tools to test their effectiveness. However, despite the studies evaluating future material requirements are increasing in number, they are usually done ex-post starting from already available energy transition scenarios. In that way, such energy scenarios are not affected by potential materials and technology supply chain bottlenecks. That makes the analysis presented here among the first-of-a-kind assessments of energy and material SRs in a multi-objective energy system optimization framework. The proposed methodology involves the consistent definition of the energy and material SRs for a reference energy system as two separate objective functions to be used in a MOO. The trade-offs between such SRs, costs and CO₂ emissions are studied through MOO optimization for a case study developed within the open-source Temoa framework, providing insights about technology competitiveness in terms of energy security.

■ TD-10

Tuesday, 14:30-16:00 - Room: 11 (building: 116)

Kidney Exchange II

Stream: OR in Health Services (ORAHS)

Invited session

Chair: Joel Joris Van de Klundert

Chair: Twan Dollevoet

1 - Evaluating policy changes to Eurotransplant's kidney allocation rules with Discrete Event Simulation

Hans de Ferrante, Bart Smeulders, Frits Spijksma

Eurotransplant (ET) prioritizes candidates for deceased-donor kidney transplantation with the ET Kidney Allocation System (ETKAS) algorithm. ETKAS is a points-based system which awards points for

patient and donor attributes, including dialysis time, HLA match quality, candidate age, relative location of the candidate w.r.t. the donor, and chances of finding a donor with at most 1 HLA mismatch in the ET donor pool.

The ET Kidney Advisory Committee (ETKAC) regularly points out that ETKAS is outdated. For instance, ETKAS still assigns equal priority to matches on HLA-A, -B and -DR loci, ETKAS does not include age matching, and ETKAS inadequately compensates immunized candidates for having a restricted donor pool. Despite recognition of such issues, the weights assigned to ETKAS attributes has changed little since ETKAS was introduced in 1996.

To facilitate ETKAC discussions on revising ETKAS, we developed the ETKAS simulator, which is a discrete event simulator based on ET registry data simulating ET kidney allocation. We find that the simulator accurately describes candidate dialysis times at transplant, mortality rates, and transplantation rates in ET member countries. To demonstrate utility of the ETKAS simulator for policy evaluation, we map the impact of assigning extra points to HLA-DR matching relative to HLA-A and HLA-B matching, as well as directly prioritizing immunized candidates by assigning points for virtual Panel Reactive Antibodies (vPRA).

2 - Wanted, Dead or Alive: Leveraging Deceased Donors for Enhanced Patient Outcomes in Kidney Exchange Programs

Roby Cremers, Twan Dollevoet, Joel Joris Van de Klundert, Michal Mankowski

Kidney transplant is crucial for end-stage renal disease patients, yet demand for kidneys surpasses supply. Organs can be obtained from both deceased and living donors, with compatibility between patient and donor being a pivotal factor in the matching process. Kidney Exchange Programs (KEPs) aim to address the kidney shortage issue by facilitating exchanges between living incompatible donor-recipient pairs, either through cycles or through chains initiated by a living donor. To boost transplant rates, the use of deceased donor kidneys to trigger transplant chains has been proposed, which involves the last donor in the chain donating back to the deceased donor waiting list. This study investigates when to use deceased donors to initiate chains, aiming to maximize the total number of transplants, while ensuring patient types on the deceased donor waiting list are not disadvantaged. First, we use an offline Integer Linear Programming framework to assess the efficacy of using deceased chain-initiating kidneys (CIKs) within the existing practice. Building on this foundation, we introduce a stochastic model using Sample Average Approximation to address the dynamic and uncertain nature of the problem. Through simulation, using secondary data from the National Kidney Registry between 2012 and 2016, we show that deceased CIKs can potentially enhance patient outcomes in terms of the number of transplants and wait times, but the results are sensitive to the characteristics of the KEP.

3 - Half-Cycle: A new formulation for modelling kidney exchange problems

David Manlove, Mathijs Barkel, Maxence Delorme, William Pettersson, Tom Smeets

A patient who requires a kidney transplant, and who has a willing but incompatible donor, may be able to 'swap' their donor with that of another patient, who is in a similar situation, in a cyclic fashion. Also, non-directed donors can trigger 'chains' of transplants involving multiple donor-recipient pairs. In this talk we introduce the Half-Cycle Formulation (HCF), an integer programming (IP) model for finding optimal sets of exchanges involving cycles and chains among incompatible donor-recipient pairs. In HCF, a cycle (i.e., set of kidney swaps) is represented by two compatible halves, and we also demonstrate how the model can be extended to incorporate chains. After giving several algorithmic enhancements for HCF, we show through computational experiments with an IP solver that our model is competitive in relation to other formulations for certain cycle and chain size limits.

4 - Synthetic data generation for kidney exchange programme simulation

William Pettersson, David Manlove

Kidney exchange programmes (KEPs) increase the potential for living kidney donation, often using operational research techniques, and drastically improving the quality of life of recipients. This is achieved by identifying an optimal set of transplants that can be performed within a pool of donor-recipient pairs via exchange cycles and chains. However, determining appropriate optimality criteria to use is not trivial, and only with historical real data or realistic synthetic data can simulations show how different criteria affect the performance of the KEP. However, historical datasets can be difficult to obtain.

In this talk we walk through the process of producing a realistic synthetic data generator from real-world data using state-of-the-art techniques. We include full Jupyter notebooks that can easily be followed by researchers associated with real-world KEPs. We then follow up by demonstrating how the data generator can be used to simulate the effects of a number of different optimality criteria on the KEP.

BOR in public policy and environmental decisions

Stream: Behavioural OR

Invited session

Chair: Judit Lienert

1 - Analysing the compensatory properties of the outranking approach PROMETHEE

Sebastian Schär, Jutta Geldermann

Compensation in multiple criteria decision aggregation procedures is commonly understood as allowing a gain in one criterion to offset a loss in another criterion. The compensatory behaviour depends on the selected multicriteria approach but can for some approaches also be steered by their specific design in terms of preference modelling and choice of aggregation logic. In domains such as environmental or public policy decision-making compensation is not always desired. There may be impacts that pose a loss too serious to be counterbalanced by any kind of good performance on other criteria. Furthermore, compensation may overshadow the existence of strong minority views. It may therefore be necessary to limit the extent to which an aggregation procedure can allow for compensation or explicitly acknowledge it. The PROMETHEE methods are increasingly applied in environmental and public policy decision making due to their comprehensiveness and explainability. However, there are different statements in the literature about their compensatory properties. Furthermore, guidelines for applicants and analysts which explain how to control and steer the degree of compensation are apparently rare and opaque. We analyse the compensatory behaviour of outranking approaches with particular emphasis on the PROMETHEE methods and compare it to that of multiple attribute value theory approaches with the aim of providing guidelines for application and preventing unwanted compensation behaviour.

2 - Preferences and risk attitudes in Swiss pesticide governance

Milena Wiget, Judit Lienert, Karin Ingold

Negative effects on human health and the environment call for ambitious policies to reduce the risks of agricultural pesticide use. Yet, strategic uncertainty exists, which is often neglected. New policies must be of utility to a range of stakeholders to be implemented. We studied how preferences for achieving multiple conflicting objectives and domain-specific risk attitudes towards uncertain consequences influence the support of new policy alternatives. To this end, we combined concepts from policy analysis and Multi-criteria Decision Analysis. We collected data on preferences, risk attitudes, and policy support from 24 key stakeholders and their collaboration partners in Swiss pesticide governance. Analyzing the data with Bayesian ordinal logistic regression models, we found specific relations between the support of certain policies and preferences, risk attitudes, or both. In wicked socio-environmental decision problems with great uncertainty,

we thus suggest considering risk attitudes additionally to preferences to develop ambitious policies with potential for a sustainable transition. Our contribution is threefold: Theoretically, we present an innovative combination of the Advocacy Coalition Framework and Multi-attribute Value/Utility Theory. Methodologically, we describe a standardized approach to elicit preferences and risk attitudes, novel to policy analysis. Practically, we discuss the potential of pesticide risk reduction policies in the case of Swiss agriculture.

3 - Advancing BOR: Structuring challenges and (inter)disciplinary approaches in the energy transition

Marta Lopes, Carlos Henggeler Antunes

The energy transition is a global priority to address climate change and ensure energy security. While technological developments play an instrumental role in enabling this transition, the importance of human behaviour cannot be understated. People's energy consumption practices significantly impact energy demand patterns. Additionally, the adoption of renewable energy technologies depends on public acceptance, and energy projects often affect communities. Operational research (OR) models and methods have been successfully employed to address several complex problems in the energy sector, such as the location of infrastructures, the energy sharing in energy communities and market design, involving multiple stakeholders, including utilities, governmental agencies, and consumers. The objective of this study is to organise the relevant operational research challenges related to the energy transition, identify the associated behavioural aspects, and examine several disciplinary approaches used to address these challenges. Ultimately, the aim is to identify research gaps, contributing to the advancement of the behavioural OR discipline.

4 - Time and behavioral implications are neglected in applied environmental decisions

Judit Lienert, Fridolin Haag, Philipp Beutler, Martijn Kuller

Time can play a decisive role in practical applications of Multi-Criteria Decision Analysis (MCDA) aiming to support environmental and other public policy decisions. When we decide about options that affect environmental (or societal) systems, we often address long time ranges. An overview of applications of MCDA published in non-OR journals (Operational Research) indicates that time is heavily neglected. What about the OR literature? A systematic search of OR journals indicates that the temporal aspect of decision-making in MCDA is also neglected in our field. In this talk, I will present some data to support this claim. Additionally, I shortly present insights from own research projects, where we have started addressing temporal aspects of decision analysis. This includes a prominent question in economics that has not been thoroughly treated in our literature: do preferences change over time; and does it matter? Furthermore, using an example from wastewater infrastructure planning, I demonstrate how we can implement MCDA in complex real-world environmental projects and include time aspects. We used a very pragmatic approach to evaluate decision options over time with MCDA, which nevertheless seemed useful to support decision-making. Various mathematical approaches to deal with temporal decision-making have been proposed, but what about behavioral aspects? I conclude by proposing research questions that could be tackled by the BOR community.

In this presentation we report on a large-scale time study to estimate the expected duration of a set of common nursing tasks in 25 Belgian hospitals involving over 600 nurses. A direct time measurement by starting and stopping a timer at the beginning and end of every executed task proved to be too invasive and complicated if done by the nurse itself and too expensive if done by an outside expert. We therefore used an indirect method by equipping each nurse with a smart phone running an application that beeps at irregular time intervals. After every beep, within a time-out interval, the nurse registers what task type she was executing. In addition, after the nurse's work shift is finished, she is presented with a list of 10 task types and asked to tally how many tasks of each type were executed during the shift. For a certain task type, the beeps allow us to estimate the fraction of time a nurse spends on tasks of this type, while the tallies estimate their rate, i.e. how many tasks of this type occur per time unit. The ratio of the fraction and rate is the expected duration.

We provide approximations of the bias and the variance of the resulting estimator using the Delta method leading to reliable confidence intervals and optimal strategies for deciding which task types to tally in future nurse shifts. In addition, we investigate the quality of our approximation by comparing to Monte Carlo simulations.

2 - Identifying the key factors of job satisfaction of the second-career certified nursing assistants in long-term care

Chien-Hui Wang, Ru-Ying Li

The aging population and declining birth rates have become social issues in many Asian countries, especially Taiwan. To alleviate the significant shortage of manpower, hiring second-career certified nursing assistants has emerged as a new trend in care institutions. This study combines interviews and the Analytic Hierarchy Process to explore the job satisfaction and key factors influencing turnover decisions of second-career care workers. The findings of this study will contribute to understanding the factors affecting job satisfaction among second-career care workers and serve as a reference for training programs in long-term care institutions.

3 - A study of flexibility and the chaining principle in the mid-term nurse scheduling problem

Diego Fiorotto, Maria Paula Padilla, Karim Martínez

The scheduling of personnel is a common problem that healthcare institutions frequently face worldwide. It consists of assigning nurses to shifts to satisfy a series of constraints relative to the workforce's skills, employee preferences and legal regulations. The current healthcare landscape, characterized by rising demand and a decreasing workforce, together with the effect that scheduling has over aspects like costs, turnovers, and job satisfaction, has become a great motivation for studying this problem. Cross-training, which consists of training nurses to cover additional units that require distinct skills, has been studied in different sectors from manufacturing to healthcare as a strategy to add flexibility to the healthcare systems and improve its responsiveness. In this paper, we study existing forms to include this type of flexibility and propose a mathematical formulation to incorporate it. Computational experiments over different scenarios show that the proposed extensions are functional and can produce solutions for the mid-term nurse scheduling problem. From the experiments, we derive some interesting insights about cross-training flexibility. First, our results show that it is more beneficial to invest in intensity, which is the number of cross-trained nurses, than investing in breadth, i.e., the number of additional units a nurse is trained to. Furthermore, there is a trade-off between flexibility and the amount of dedicated working time for each unit.

1 - Top Players Prediction in Football: Interesting Facts on Data Preparation and Analysis

Senthil Murugan Nagarajan

In the dynamic landscape of football, predicting the emergence and success of top players is a crucial aspect that has gained momentum with the advent of advanced analytics. This presentation explores the fascinating world of forecasting top players in football, focusing on the intriguing facts surrounding data preparation and analysis. By delving into the intricacies of collecting and processing vast datasets, this presentation unveils the methodologies employed to identify key performance indicators and potential breakthrough talents. Leveraging cutting-edge analytics, teams and analysts aim to unravel patterns and trends that transcend traditional scouting methods. This talk highlights the synergy between technology and talent evaluation, offering insights into the challenges, breakthroughs, and captivating facts that define the landscape of predicting top players in football.

2 - Data science models for football scouting: the Racing de Santander case study

Manuel Duran, Diego Brunetti, Sebastián Ceria, Guillermo Durán, Andrés Farall, Nicolás Marucho, Pablo Mislej

The use of data to improve the performance and operation of sports institutions is increasingly expanding. Related to scouting, the most renowned case is that of Moneyball, which summarizes the successful use of data to improve the performance of a US professional baseball team that had a much smaller budget than that of most of its opponents. In this work we apply different data science techniques to improve the scouting of a professional soccer team. In particular, we attack the problem of similarity between players, so that a sports manager can have information about who is the player most similar to someone he has to replace, or who he cannot access due to a budgetary issue. Various similarity schemes were employed to compare players by considering their specific individual characteristics as covariates. Some approaches adopted a non-supervised perspective, while others utilized supervised models that incorporated valuable information obtained from the players' known positions on the field as a target for supervision. The disparity between these contrasting approaches yielded complementary results. We take as a case study that of the Real Racing Club de Santander, from Spain Second Division,

3 - TOPSIS++: A New Approach for Player Recruitment and Selection in Team Sports

Mark Connor

Player recruitment and selection is one of the most important factors in determining the success of a team. The recruitment process is a complex task that involves considering various factors (form, fitness, etc) whilst being constrained by the team's budget and the availability of players in the market. The recruitment process is further complicated by the fact that the performance level of a player is not static and can change over time. Therefore, it is important to consider both the players current form and the player's future form in recruitment and selection decisions. In this paper, we propose a new approach for player selection and recruitment in team sports. TOPSIS++ is an extension of the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) method that is widely used in decision-making problems. TOPSIS++ is designed to address the limitations of the original TOPSIS method by considering not just a player's current form but also their previous and future predicted form. We demonstrate the effectiveness of TOPSIS++ by applying it to the problem of player selection and recruitment in football. We compare the performance of TOPSIS++ with the original TOPSIS method and show that TOPSIS++

performs better in terms of identifying the best player to recruit when evaluated against the actual performance of the players in preceding seasons. Our results show that TOPSIS++ is a promising approach for player selection and recruitment in team sports.

4 - Should he stay or should he go? Head Coach turnover and cultural disparities in the market for managers - Empirical Evidence from European Professional Football

Felix Sage

When a football team is experiencing a sporting downturn, there are limited short-term options available from the club's management perspective. Building a better-performing squad in the short run is not feasible. Another potential adjustment is to change the team's head coach. This analogy can be transferred to leaders managing any organization. We focus on the question of which characteristics are attributed to a successful long-term leader. The paper investigates the impact of team performance and individual characteristics of the coach on the coach's tenure. For this purpose, we use various data from the top five European leagues (first and second division) from the 2012/13 to the 2022/23 season. In order to adequately analyze this impact, we use elaborate competing risk models to identify the effect of cultural differences on various reasons of coach dismissals. The data is gathered at the matchday level and thus obtained a dataset covering 43,985 match-days. To our knowledge, we are the first to simultaneously examine these effects across ten different European leagues over a decade. Just like the modern cooperation, most football teams consist of employees (players and head coaches) of different cultures producing language barriers which can particularly lead to communication and transaction costs. The unique dataset allows us to include these cultural and linguistic effects that could impact team performance, coach's performance, and ultimately, the coach's tenure.

1 - A reinforcement learning mechanism for trading wind power futures

Bruno Kamdem, Moustapha Pemy

Recent developments in Europe have disrupted gas supplies and reignited the urgency of moving towards electricity production from winds. But, the narrow predictability of wind and the intermittency of electricity generation can complicate decisions within trading desks. To alleviate the issue at hand, an attempt in this paper is to provide an optimal trading mechanism by accounting seasonalities in wind productions as electricity sells in the exchange. We formulate the problem from a standpoint of an institutional investor concerned with ESG factors. For the trader, we define his reward at each future price after a number of trades. We introduce a parametrized approximate value function using deep convolutional neural network in which we specify the weights of the Q-network at each iteration. We derive some key implications for the trader as to the best time to buy wind power futures and at what price to do it.

2 - Generative South African ESG indexes and multi-target neural complexity in return prediction

Gordon Dash, Nina Kajiji, Bruno Kamdem

A company's dedication to environmental, social, and governance principles (ESG) has led to an interest in developing and evaluating firm-level ESG scores. Despite the considerable interest in assessing firm-level scores, investment analytics lack standardized country-specific ESG indexes to comprehensively represent sustainability while facilitating asset predictability. This deficiency is noticeable in the emerging BRICS capital markets (i.e., Brazil, Russia, India, China, and South Africa (SA)). Focusing on SA, the primary objective of this study is to formulate an innovative algorithmic framework to identify distinct dynamic ESG factors capable of assessing sustainability risk in securities traded on the Johannesburg Stock Exchange (JSE). The proposed alternative data procedure utilizes asset returns in the exploratory factor analysis to generate maximum validity factor scores to formulate JSE-specific sustainability factors. The effectiveness of these factors is assessed through a machine-learning model operating within a complex information space that considers the interconnections of valuation signals. Employing an explainable AI technique (XAI), we determine that the newly created S-factor emerges as the primary feature for explaining next-period returns. Following closely behind is the E factor, the SA volatility index, and a precious metals factor. XAI reveals that these factors excel at discerning the varying emphasis South African firms place on their ESG signals.

3 - Optimizing post-pandemic recovery: a comparative analysis of machine learning techniques for tourism SMMEs revenue predictive modelling

Helper Zhou, Gordon Dash, Nina Kajiji, Mabutho Sibanda

The COVID-19 pandemic dramatically affected global tourism, especially South African tour operating Small, Medium, and Micro Enterprises (SMMEs). These enterprises are now leveraging machine learning (ML) to make informed decisions using predictive models. However, choosing the right ML technique is challenging for these operators due to their limited technical expertise. This study compares shallow and deep learning methods for predicting tour operator performance, using a dataset from 650 South African SMMEs, spanning 2019-2021. The enhanced radial basis function (K4-RANN), a shallow learning model, outperformed deep learning models, showing better prediction accuracy with lower error rates and higher R^2 values. Therefore, the study recommends that tourism SMMEs adopt the K4-RANN model for more accurate booking and revenue projections, thereby improving decision-making and efficiency post the Covid-19 pandemic era.

4 - Investors' perception of firms' ESG focus: Evidence from staggered implementations of Benefit Corporations law in the US

Laura Ferraro, Devendra Kale, Anis Triki

Benefit Corporations (BC) pursue a dual purpose: maximization of profits and generating societal and environmental benefits. BCs are becoming popular across the globe, with BC laws being passed in different countries. To date, BC laws have been passed in 43 US states and several countries in Europe and South America. Using the staggered adoption of BC law across US states, we examine how investors reacted to this law. We find that investors reacted negatively to the passing of the law. Our results are robust in using alternate measures of abnormal returns and excluding firms in the financial services sector. Moreover, our results are robust regarding entropy balancing the three moments. This suggests that investors in the US do not favor corporations adopting a dual purpose (as opposed to a solo focus on profit maximization). We further find that the negative reaction is predominantly for smaller and loss-making firms. Since most of the BCs in the US are, in fact, small in size, investors expect smaller firms to adopt the BC status. We also find that investors' negative reactions softened after the onset of the COVID pandemic when the focus on ESG saw an exponential increase. As an additional analysis, we are replicating our work in the Italian context, as it was the first European country to adopt the BC law. Our results are significant for stakeholders, including investors, boards, regulators, and analysts.

Decomposition techniques applied to energy problems

Stream: OR in Energy

Invited session

Chair: [Angela Flores](#)

1 - Decomposing stochastic energy system optimization models - time-splitting in Benders Decomposition vs. PIPS-IPM++

Shima Sasanpour, Manuel Wetzal, Karl-Kiên Cao, Andres Ramos

Energy system optimization models (ESOMs) are a helpful tool to design future energy systems. Although uncertainties in the input data assumptions can significantly influence the structure of the energy system, they remain unconsidered in many cases. Through the application of stochastic programming (SP) it is possible to obtain expansion decisions that offer risk hedging with regard to the uncertainty of future developments. ESOMs become large in size when a broad regional scope and technological diversity for sector coupling are considered, even without taking uncertainties into account. Therefore, speed-up techniques are needed to keep the models solvable, especially if SP is additionally considered. Benders Decomposition (BD) is a widely used method to solve SP models since the second stage can be solved in independent subproblems, allowing for a parallelization along the stochastic scenario dimension. However, the cardinality of the scenario set is usually much smaller than the number of time steps. In our analysis we expand the parallelization potential of stochastic ESOMs by additionally splitting the scenarios along the time dimension. We apply this decomposition technique to two methods: First, we consider time-splitting in BD in combination with MPI. This is then compared to the parallel high-performance computing solver PIPS-IPM++, which was recently extended to also consider stochastic optimization, allowing a decomposition along the scenario and time dimension.

2 - Analyzing decomposition approaches for large-scale energy system models

Lene Marie Grübler, Felix Muesgens

The share of renewable energy generation capacities will rise substantially in the upcoming decades, which requires the expansion of power grids and storage solutions. Current research therefore often aims at jointly optimizing expansion and operation of generators, storages and grid infrastructure, resulting in complex optimization problems to be solved. Their structure reveals decomposability on the temporal as well as on the spatial scale, which allows the application of decomposition techniques to keep them computationally tractable. While investment decisions spanning over multiple time steps represent complicating variables on the temporal scale, constraints describing inter-regional power exchanges represent complicating constraints on the spatial scale. Previous decomposition approaches in energy system modelling have either been performed on the temporal or on the spatial scale, but combined approaches have not yet been investigated. As energy system models hold complicating variables and constraints, there exist numerous possible decompositions of the original problem, which may be solved by different decomposition techniques. In this work we analyze which techniques are most efficient in optimizing large-scale multi-regional energy systems. We deliver a case study for the comparison of different decomposition strategies for a specific problem type and contribute to the open question of which decompositions are most suitable for which type of optimization problems.

3 - Hybrid decomposition method for power system planning under uncertainty

Angela Flores

Integrating both short-term flexibility requirements and long-term uncertainty into a unified planning framework results in large-scale multi-stage stochastic mixed-integer programming problems. Consequently, efficient solution methodologies are needed to enable the planning of realistic-size power systems. This work investigates possible ways of combining column generation, lagrangian relaxation, and Benders decomposition in a hybrid decomposition method, aiming to enhance convergence by leveraging the strengths of diverse decomposition techniques. The proposed hybrid decomposition is implemented using distributed computing, allowing parallel initiation of each decomposition approach with the potential for exchanging bounds and solutions. Solutions from Benders decomposition and the bundle method at each iteration can be used to generate new columns for the column generation approach. Likewise, the columns obtained by column generation can be used to derive new cuts for Benders decomposition and the bundle method. The performance of the hybrid decomposition is analyzed through case studies applied to the NREL 118-bus power system.

Advancements in AI and Genomics: Bridging Technology and Biology for Future Healthcare Solutions

Stream: Computational Biology, Bioinformatics and Medicine

Invited session

Chair: [Aleksandra Swiercz](#)

1 - AI-powered lab-on-a-chip platform for rapid bacterial detection

Felipe Tetsuo Yamada, Flávia Barbosa, Luis Guimarães

Antimicrobial resistance (AMR) presents a serious threat to public health by undermining the efficacy of antibiotic treatments, leading to prolonged illness and heightened healthcare costs. Nearly 5 million deaths occur annually due to drug-resistant infections, with the European Union recording over 33,000 fatalities yearly, coupled with an economic impact exceeding EUR 1.5 billion annually in healthcare expenses and productivity loss. The widespread misuse of antibiotics across various sectors, including human medicine, animal husbandry, and agriculture, coupled with inadequate infection prevention and control measures, fuels the proliferation of resistant bacteria, driving the AMR crisis. Addressing AMR in bacteria requires concerted actions to promote judicious antibiotic usage, enhance infection prevention and control protocols, develop new antibiotics, and bolster surveillance systems to monitor resistance trends effectively. Utilizing molecular detection techniques, this study employs a microfluidic lab-on-a-chip device with DNA and bacteriophage proteins as bio-recognition molecules. The device generates unique signals for different fluid compositions. The aim is to develop a machine learning model capable of analyzing these signals, thereby aiding in the detection and monitoring of bacteria and AMR genes during infections. Ultimately, this will improve antibiotic prescribing decisions in both human and animal healthcare.

2 - Genomic Map of Poland versus artificial intelligence - opportunities, challenges and threats

Piotr Lukasiak, Aleksandra Swiercz, Maciej Majchrzak, Jacek Blazewicz

Computing, together with computational tools supported by machine learning, plays a key role in the creation of national genomic maps by

enabling the analysis, interpretation and use of vast amounts of genetic information from multiple sources. Operations research methods are essential for understanding the genetic diversity of populations and for advances in personalised medicine and disease inheritance research. They influence the modelling processes of genome sequencing, comparison with reference genomes, identification of genetic variants and assessment of their functional consequences. Data processing enables the integration of genetic information from different sources, enabling the understanding of the relationships between genetic variation and phenotypic traits and diseases, as well as the identification of population structure and the analysis of genetic relationships between individuals in a population. The Genomic Map of Poland is a set of unique databases of genomic sequences reflecting the genetic picture of the Polish population, together with computational and visualisation tools that allow the analysis and interpretation of large amounts of genetic data and the integration of different sources of information, leading to an understanding of the genetic diversity of the population and the identification of relationships between genes and phenotypic traits and diseases.

3 - Assessment of the quality of de novo assembled genome

Aleksandra Swiercz, Alicja Dzik, Piotr Lukasiak, Jacek Blazewicz

The first draft of the human genome project was published more than two decades ago. It was incomplete, especially in the centromeric and telomeric regions, which are highly repetitive. With the development of third-generation technology, it has become possible to fill most of the gaps in the reference genome (T2T consortium). However, long-read technologies can cover large portions of the genome, but this involves higher error rates. Thus, de novo sequencing projects often use different sequencing technologies to, on the one hand, obtain long DNA fragments and, on the other hand, improve the sequence quality with short reads.

In the Genomic Map of Poland project, we used a pipeline to construct de novo a diploid human genome based on the trio: mother, father and child. We used several technologies in the pipeline: short reads, PacBio HiFi, Hi-C and ultra-long Nanopore. The resulting chromosome-wide scaffolds were compared to reference genomes (GRCH38 and CHM13). We then assessed the quality of our reference genome assembly by analyzing the consistency of k-mers appearing in the genome sequence and in short and long reads. It was also checked whether k-mers specific to only one of the parents (mother or father) occur in the copy of the chromosome inherited from one parent (each copy of the chromosome contains small differences in the sequence, specific to the individual). Various k-mer features indicate the high quality of the assembled genome.

Chair: [Anna Nagurney](#)

1 - Towards Effective Assignment Decision-Making in Refugee Resettlement

Jésica de Armas, Valérie Bélanger, Marie-Ève Rancourt, Gilbert Laporte

The number of asylum applications in the European Union (EU) has significantly increased during the last years, highlighting the need for effective decision-making in the resettlement process. This research focuses on the refugee status, the most common outcome among asylum seekers, and the resettlement process that transfers refugees from an asylum country to a receiving country. Integration plays a crucial role in the success of resettlement, benefiting both refugees and receiving countries. Efforts from all parties, including refugees' adaptation and receiving communities' readiness, are necessary for successful integration. The National Integration Evaluation Mechanism

project evaluates the integration outcomes of refugees in 15 EU member states, providing a comprehensive overview through a set of integration indicators. The priorities of receiving countries and the preferences of refugees also influence the assignment process. However, no comprehensive optimization framework exists that combines these dimensions for decision support. This study proposes a decision-making system that incorporates integration potential, receiving countries' priorities, and refugees' preferences, considering quotas and analyzing different scenarios. The system aims to aid organizations in making informed decisions and could be integrated into existing information systems. The research contributes to addressing the complex challenges of refugee resettlement and has potential societal impact.

2 - Decentralization Approach for Global Relocation Planning under Climate Change

Kash Barker, Buket Cilali, Andres Gonzalez, Ahti Salo

The upcoming climate crisis is a consequential driver for displacement of communities, a little-studied problem in operations research. Its effects would strike people worldwide, causing displacement in great quantities. The unique characteristics of this problem - including consideration of a long-term planning horizon, future uncertainties, and heterogeneous populations and numerous locations under different climate change impacts at varying levels - require a different approach to handle this problem. For these reasons, our approach can assist in developing relocation plans to manage climate-change-induced movements with a long-term outlook while using the resources effectively and protecting the well-being and dignity of both displaced and receiving communities. The first step of these plans is the high-level planning of where the displaced people should go and when. The second step reflects the mixed decision-making structure resulting from the involvement of many local authorities and the necessity of looking after global humanitarian interests. We suggest a consensus structure that compromises the global outcomes and local interests using a global optimal model, self-optimal local models, and a final global model that uses the outputs of the global and self-optimal models and iterates by adjusting the decisions until fairness among all participating hosts is achieved.

3 - Health Product Availability in the Presence of Cash Constraints: A Study of Community Health Entrepreneurs in Rural Kenya

Lisanne van Rijn, Harwin de Vries, Lucas Veelenturf

Access to essential medicines and other health products remains a challenge in low- and middle-income countries, particularly in rural areas. Community health entrepreneurs (CHEs) play a key role in bridging this gap by selling health products in small rural stores. However, CHEs frequently experience stock-outs due to cash constraints, leading to lost sales. How to relieve cash constraints in rural areas is currently unclear. We address this question by conducting a field experiment that tests two interventions with 458 CHEs in Kenya in collaboration with social enterprise Healthy Entrepreneurs. The first intervention involved setting up stock-hubs. These are small consignment stock locations where CHEs can replenish their inventory on-the-spot, thereby reducing the need for cash-on-hand. The second intervention is a cashflow game designed to help CHEs realize the value of retaining money in their business, thereby improving their cashflow resulting from increased sales. Although both interventions yielded positive effects on CHE sales, they were not statistically significant. The cost of accessing the hub and informational barriers limited CHEs' ability to fully utilize the stock-hubs. The results of the cashflow game highlighted the need for additional measures beyond raising awareness to address cash constraints effectively. This study provides valuable new insights into addressing cash constraints in areas with high resupply costs and long resupply intervals.

4 - Quantification of International Trade Network Performance Under Disruptions to Supply, Transportation, and Demand Capacity, and Exchange Rates in Disasters

Anna Nagurney, Dana Hassani, Oleg Nivievskiy, Pavlo Martyshhev

Both sudden-onset and slow-onset disasters are causing disruptions to global trade, impacting the availability and affordability of commodities from agricultural to mineral ones. In this paper, we develop a multicommodity international trade network equilibrium model under disaster scenarios with distinct probabilities of the occurrence of the disasters and their impacts on the capacities associated with production, transportation, and consumption. The disaster scenarios can also affect the exchange rates. We state the governing equilibrium conditions and derive the variational inequality formulation in commodity path flow variables and Lagrange multipliers associated with the capacity constraints. For each disaster scenario, we construct an international trade network performance measure, an international trade network performance measure, followed by a unified performance measure that includes all the disasters and their probabilities. Robustness is then quantified as the difference between the network performance under no disruptions and the unified performance measure. An international trade network component performance indicator is also given to assess the impacts of the complete removal of trade network supply markets, demand markets, and/or transportation routes. The modeling framework is then illustrated through a series of numerical examples, motivated by Russia's war on Ukraine. The work is of relevance to decision-makers and policy-makers.

Tuesday, 14:30-16:00 - Room: 81 (building: 116)

Distributed energy systems

Stream: Energy Management

Invited session

Chair: Juana Lopez Redondo

1 - Multi-objective optimization for a microgrid energy management system: Controlling battery lifetime and economic cost.

Juana Lopez Redondo, Luis Polanco, Víctor M. Ramírez, José Luis Torres, J.d. Álvarez

Batteries are the element of the microgrid with the shortest and limited lifetime, characterized by a finite number of charge/discharge cycles. By optimizing charge/discharge cycles, the system can extend battery life, contributing to overall sustainability. However, in microgrids, it is often in the interest of minimizing their economic operating cost, which is a contradictory objective to maximizing battery lifetime, as batteries can save energy from renewable energy sources for use during periods of high energy demand instead of using energy from the main grid. Therefore, the energy management system must address these objectives to ensure efficient operation of the microgrid. This research presents a novel energy management system designed to simultaneously minimize energy costs and battery charge/discharge cycles in a microgrid. Our methodology employs a multi-objective optimization algorithm to identify solutions that satisfy both economic and operational objectives. The result is a set of equally valuable solutions, giving decision makers the flexibility to choose the option that best fits their current preferences. This adaptability allows users or operators to change solutions as conditions evolve, eliminating the need to re-solve the optimization problem. The effectiveness of the energy management system is demonstrated through its application in simulation to the microgrid located in a bioclimatic building at the University of Almería.

2 - Empowering Energy Exchange: A Tri-Level Decentralized Coordination Framework for TSOs, DSOs, and DERs

Tolga Karabas, Meltem Peker, Mustafa Kemal Tural

With the proliferation of Distributed Energy Resources (DERs) in power grids, the transition to bidirectional power flow challenges traditional unidirectional energy systems. The uncertain nature of renewable DERs further escalates the complexity of energy management. Despite these challenges, DERs offer valuable energy and flexibility

services to power grids. This study proposes a novel tri-level decentralized transactive energy market framework to address these complexities. In this framework, Distribution System Operators (DSOs) are positioned as key distribution-level local energy market coordinators and serve as crucial intermediaries, facilitating communication between Transmission System Operators (TSOs) and DERs through network-aware pricing and transactive control mechanisms. By allowing DER participation through optimized bidding strategies in local energy markets (and indirectly in wholesale markets via DSOs), the framework aims to optimize system operations while accounting for uncertainty through distributionally robust optimization methods. Thus, it presents a promising avenue for enhancing grid security and reliability through the proposed distributionally robust unit commitment and optimal power flow problems. By considering the dynamic interactions among TSOs, DSOs, and DERs, the proposed coordination approach aims to lay the groundwork for a more resilient and efficient energy system management with optimized grid operations.

3 - Improving the Battery Model for Energy Management Systems in Microgrid Applications

Cesar Cerda, Rodrigo A. Carrasco

The adoption of non-conventional renewable energy sources (NCRE) is essential to achieve the Paris Agreement's objectives. This transformation does not only involve changing the primary energy source of large-scale electricity generation but, its effective adoption requires changes at the level of the energy transportation and distribution network, including NCRE distributed generation and microgrids systems to provide stability to the grid. Since NCRE are generally variable, energy storage and energy management systems (EMS) has become key allies on this process. In this talk we present how improvements on mathematical model for battery storage in EMS for microgrid applications can produce better decisions, reducing the microgrid operation costs significantly. For this purpose, a new battery model (MLPP-A) is presented, which incorporates the nonlinearities of the battery charging process through a piecewise linear approximation. Our MLPP-A model is benchmarked against a linear battery charging model (MLB), to get the parameters for both models experimentally, and to compare their adjustment with real system, a microgrid test bed was implemented. To evaluate the EMS performance with both battery models, under same solar irradiance conditions, on different seasons of the year, a computational simulation was implemented, which showed an average economic benefit of 6.33% once MLPP-A model is used instead of MLB model, without significant additional computing time required.

4 - Incorporating two-stage stochastic programming in the optimal scheduling of an offshore off-grid power-to-X system

Maximilian Fey, Lorenz Häfele, Kai Hufendiek

Offshore off-grid power-to-X (PtX) processes are gaining research interest due to their potential in unlocking untapped renewable energy sources and meeting the growing demand for green hydrogen and its derivatives. However, the inflexibility of the chemical processes involved, coupled with the stochastic nature of wind power production as the sole energy source, poses significant operational challenges. Despite the buffering function of energy and material storages included in the system, the inherent uncertainty in wind power generation complicates the assurance of safe and continuous operation, given the narrow operational windows and low ramp rates. Commonly proposed predictive control solutions, such as model predictive control (MPC), often overlook the uncertainty from wind power forecast deviations, which is particularly significant offshore. We propose a novel MILP-based MPC framework that incorporates two-stage stochastic programming to address this uncertainty. The framework generates scenarios using an ARMA model based on deterministic wind forecasts and reported statistical error characteristics. This approach aims to enhance the operational efficiency of off-grid PtX processes, thereby increasing their load factor, product yield, and competitiveness. It is expected to facilitate wide-scale deployment of these processes, contributing in the transformation towards a fossil-free economy.

1 - The impact of supply shortage and uncertainty on product design for remanufacturing in a closed-loop supply chain

Tanja Mlinar, Maud Van den Broeke, Roya Tat

Nowadays, companies are increasingly confronted with shortages and uncertainty in supply of raw materials. At the same time, in light of sustainability, supply chains are increasingly interested in returning used products from customers and remanufacturing them. We develop an analytical model in a closed-loop supply chain context to study how shortages and uncertainty in supply impact different supply chain decisions. We focus on a supply chain with a (re)manufacturer and collector as decision-makers. The manufacturer offers products (produced from scratch or through re-manufacturing) and then sells them to the customers (i.e., forward flow). They also make product design investment decisions which affect remanufacturing costs, and set the products' selling prices. The collector incentivizes consumers to return used products, collects them (i.e., return flow), and sells them to the (re)-manufacturer who uses them for the purpose of remanufacturing. We provide managers with insights on these decisions under a decentralized and centralized setting under supply shortage and uncertainty, and conduct a sensitivity analysis with respect to various parameters.

2 - Optimal Processing and Pricing Policies in a Mobile Phone Refurbishment System

Osman Kulak, Martin Grunow

The market for refurbished phones provides significant opportunities for efficiently reusing scarce resources and grows rapidly. In such a circular supply chain system, purchasing, refurbishment, and sales are directly affected by a highly dynamic environment with fluctuating prices and demands. To maximize the long-term average profit in the refurbishment system, determination of the optimal purchasing, processing, and sales strategies is required. We propose a linear programming formulation for a Markov Decision Process that considers the arrival of multiple-raw materials and investigate how the sales price and purchasing price variations, the correlation between sales and purchasing prices, and limited capacities for semi-finished and finished goods inventory and for refurbishment affect the considered supply chain for refurbished mobile phones. Our numerical experiments use industry data and lead to critical managerial insights for our industry partner.

3 - How Marginal Value of Time Influences Optimality when Remanufacturing to Multiple Generations

Neil Geismar

Because a product's value decays over time, recovered items (cores) cannot regain their original value when remanufactured—even if kept in pristine condition. We consider a Remanufacturing Original Equipment Manufacturer who can remanufacture recovered cores to their original configuration or upgrade them to current technology. He sells new and remanufactured items concurrently. Each production period signifies an upgrade of the product's features to a new technological generation.

We use our novel modeling of Marginal Value of Time (MVT) to perform a rigorous structural decomposition over all potentially optimal values of costs, consumers' valuations, core availability, and MVT to determine conditions under which cores should be restored to their original configuration and those conditions under which cores should be upgraded to current technology. We also show that for only a very small region of the parameter space (1.58% of remanufacturing

instances) does concurrently offering both generations of remanufactured units provide greater profit than does remanufacturing to the optimal single generation. Furthermore, the average improvement in these instances is negligible (0.42%).

Sustainable Food and Health Care Logistics

Stream: Sustainable Supply Chains

Invited session

Chair: [Caroline Prodhon](#)

1 - Simulation Optimization-based Decision Support System to Enable More Local Food in the Gastronomy Sector

Suad Saliju, Christian Fikar, Christine Mendoza Pardo, Claudia Paciarotti

Recent calls for more sustainable practices in the food industry, eating healthier, and the desire to support regional farmers and rural communities, have seen an increase in the demand for local food. Particularly in the gastronomy sector, many restaurants have started offering more local food as a result of such trends. Despite various potential benefits of offering local food, real-world implementation settings often fail due to challenges in logistics operations. To enable efficient and sustainable logistics operations in the sale of local food in the gastronomy sector, this work investigates innovative and sustainable logistics concepts through the development of a simulation and optimization-based decision support system (DSS). Using the DSS, various logistics concepts are implemented and tested on two pilot areas in Bavaria, Germany and one pilot area in Marche, Italy. Preliminary results highlight potential benefits translated into shorter distances, better vehicle utilization, improved food quality, and lower lead times.

2 - The Value of Speed and Equity - Should Drones Be Used to Deliver Goods or are Better Solutions Available?: Case Studies from the UK

Andy Oakey, Antonio Martinez Sykora, Tom Cherrett

The UK's NHS is actively looking at how more sustainable and innovative transport modes can be used alongside traditional logistics systems to support their target of reaching net-zero emissions by 2040. Uncrewed Aerial Vehicles (UAVs, or drones) are increasingly being trialled in health care systems outside the UK, though evidence from previous studies and trials is suggesting that they may not be the complete answer to many of the industry's challenges. Using on-going case study investigations of local NHS same-day logistics networks in the UK region, this paper evaluates the benefits and costs of introducing mixed-mode logistics with UAVs to existing operations. Covering dense urban areas and sparse rural island areas, real-world datasets and realistic operating conditions are assessed using a novel savings algorithm and bin packing algorithm. Implications and recommendations for the wider logistics industry are subsequently given, including suggestions of where UAVs may be most applicable, and the best mode selections for different objectives and environments. The research is being undertaken as part of the and EPSRC e-Drone project.

3 - Should the Governments Charge a Carbon Tax from Servitizing Firms?

Mehmet Alegoz

Carbon tax is one of the widely used emission policies to encourage companies to decrease their emissions. Although numerous attempts have been made to investigate the effects of a carbon tax policy on the traditional selling business model, the effects of this policy on the servitizing business model, in which the firms sell the use or the outcome of a product, remain as an important research gap. Motivated

by this fact, this study proposes Stackelberg Game models to investigate the economic, environmental, and social effects of a carbon tax policy on the servitizing firms. Equilibrium results reveal that carbon tax yields an increase in the usage fee, and thus aggregate usage in the market decreases as a result of working under a carbon tax policy. This decrease in aggregate usage, on the one hand, yields a decrease in the environmental impact, and on the other hand, deteriorates the servitizing firm's profit.

4 - Sharing deliveries in a short food logistic context

Adrien Callico, Pierre Desport, Caroline Prodhon, Jean-Charles Billaut

A food supply chain qualifies as "short and local" when it is characterized by a short physical distance between producers and consumers, with no more than a single intermediary between them. Such a configuration is referred to as the "short local food supply chain" (SLFSC). Our focus lies in examining the logistical problems associated with the SLFSC. Producers often set up organizations to simplify their logistical operations. For instance, they create producers's stores, design nodal points for third-party logistics operators to collect goods, or engage in reciprocal assistance. Our study focuses on the latter type of cooperation. We consider that a producer is authorized to transport goods from one another to customers. This practice is now possible in France for short distances, specific products and limited quantities. In the case where a customer C orders products from producers A and B, two collaborative cases may arise: producer A delivers to customer C after retrieving goods coming from producer B, or producer A drops off his own goods to producer B, and the latter delivers customer C. We model this new delivery sharing problem and present our first results.

1 - Enhancing Wi-Fi Fingerprinting through the Use of an Automated Supervised Autoencoder

Tiny Du Toit

Indoor localisation is an essential area with vast implications for navigation, emergency services, and a range of Internet of Things contexts. The challenge lies in the intricate nature of indoor spaces and the limitations inherent in current technologies for precise indoor localisation. This research addresses these issues using a supervised autoencoder (SAE) approach on the UjiIndoorLoc dataset, encompassing Wi-Fi fingerprint data from various buildings and levels at Jaume I University. An AutoML search was employed to identify the best hyperparameters, including learning rate, number of epochs, layers in both the autoencoder and multilayer perceptron, nodes per layer, and dropout rate. Bayesian optimisation, an efficient search strategy, was used to test different hyperparameter combinations and neural network layer configurations to find the most effective models. The findings demonstrate the model's high accuracy rates: 99.91% for building identification, 91.45% for floor identification, and an overall accuracy of 91.18%. The SAE model's performance showcases its capability and competitive edge over a standard model and various methods, underscoring its potential to overcome the difficulties of complex indoor localisation tasks.

2 - Artificial intelligence techniques for designing conformal cooling channels for injection moulding using Moldex3D

Antonio Gaspar-Cunha, João Melo, Tomás Marques, António Pontes

Designing moulds for injection moulding is a decisive step given the complexity of some plastic parts produced by this process. The correct design principles must be followed to prevent the existence of defects that make the parts worthless. This includes short shots, flash, sink marks, warpage, weld lines and air traps, which can be avoided or minimized by the adoption of various measures, including optimizing the process parameters and using high-quality moulds. However, the presence of a high number of design variables related to the different phases of the process makes this a difficult task, principally because these variables are of different types: i) operating conditions; ii) mould design, including filling channels, number of gates and cavity; and iii) variables that depend on the machine used. Therefore, the use of numerical modelling programs was usually adopted to obtain relevant information on the injection moulding process and to enable the engineer to increase the speed of the development process. Given the high quantity of data generated and the high number of decision variables and objectives involved more sophisticated data analysis is required. The objective of this work is to develop and implement data mining techniques and surrogate models based on Artificial Neural Networks to optimize the cooling phase. Different methodologies will be tested and the hyperparameters of the methods used will be assessed to select the best model to use.

3 - Neural style transfer inspired optimisation

Stephan Nel

In the case of traditional neural style transfer, the aim is to transfer the style embedded within an image, song, or literary work to that of another, e.g. to transfer the art style of Van Gogh's *Starry Night* to another image. Contemporary approaches have demonstrated notable efficacy in respect of capturing and translating embedded properties within complex data representations. In this study, an investigation is carried out into the application of neural style transfer to optimisation algorithms. More specifically, the extent to which neural style transfer can capture and transfer salient features of high-quality solutions to other solutions is investigated. The proposed approach entails various modifications to different facets of conventional neural style transfer, such as data set construction, solution encoding, neural architecture, and loss functions. Different benchmark optimisation problems are considered in respect of evaluating the utility of the proposed approach.

Chair: *Lavinia Amorosi*

1 - Optimizing Seal Pup Counting Operations: A Novel Drone Routing Application

Anunziata Esposito Amideo, Lavinia Amorosi, Daire Carroll, Paula Carroll

Effective wildlife conservation relies on our ability to document changes in species abundance. Drones are commonly used to monitor wildlife numbers, such as the number of seals born during annual breeding aggregations. Within this context, we address harbour seal population monitoring as the Drone Routing Problem (DRP). Given a set of islands (as locations) and an equal technology drone fleet, we aim to minimize the travel energy cost associated with routing while complying with drone energy limitations (i.e., battery consumption). We model the DRP as a Mixed Integer Linear Program (MILP) resulting in a variant of the well-known Capacitated Vehicle Routing Problem (CVRP) model accounting for the relevant energy requirements. We also consider different drone cruising velocities and potential wind uncertainty. We solve the proposed MILP and present preliminary experimental results for a real-world application: monitoring seal pup production in Kosterhavet National Park, Sweden.

2 - A time-space network model for a truck and drones delivery system

Dell'Olmo Paolo, Lavinia Amorosi, Justo Puerto, Carlos Valverde

We present a bi-objective multi-period mixed integer linear programming formulation based on a time-space network for a delivery problem with an automated mothership and a fleet of drones. The proposed formulation integrates not only the routing and the scheduling problems underlying the delivery, but also the charging cycles of drone batteries with the movements of the mothership. The two objective functions are the minimization of the mothership and UAVs energy consumption and the maximization of the number of served customers. Indeed, it is assumed that not all customers can be served within the time horizon under consideration. Experimental results on a testbed of artificial instances will be presented.

3 - Developing a Sustainable Walk-and-Drive Tourism Recommendation System for Sports Mega-Events

Elham Jelodari, Sami Benjabeur

Participating in sports events has a rich history, from the ancient Olympics to today's global mega-events. In real-world scenarios, tourists attending sports events also desire to visit attractions during their stay. Tourist planning systems often integrate road and pedestrian networks to minimize transportation costs and greenhouse gas (GHG) emissions. Indeed, reducing annual tourism carbon emissions is a challenging objective due to infrastructure lock-in effects. In our research, tourists move to various Points of Interest (PoIs) or sports events, either by walking or driving, according to their preferred periods, considering time windows, and then are picked up from nearby locations. This variant of the delivery and pickup problem allows tourists to switch between walking and driving in different periods. Our contribution aims to develop a decision support system for tourists attending sports mega-events, offering opportunities to explore PoIs and participate in sports events. We present a mixed-integer linear programming formulation for the multi-period green delivery and pickup problem with time windows, aiming to maximize profit and minimize GHG emissions. We solve this problem using a new Hybrid ALNS algorithm and evaluate its performance against NSGA-II on real tourism data for Paris, focusing on the 2024 Paris Olympics. Finally, we offer insights for tourist agency managers through various analyses.

4 - On the Hierarchical Directed Capacitated Arc Routing Problem

Thu Huong Dang, Minh Hoang Ha, Trung Thanh Nguyen, André Langevin

The Hierarchical Directed Capacitated Arc Routing Problems (HDCARP) is a variant of the Capacitated Arc Routing Problems (CARPs), in which the arcs in a graph are partitioned into priority classes. However, unlike traditional CARPs that aim to minimize total time, the HDCARP focuses on minimizing the maximum completion time of each priority class in a hierarchical fashion. Practical applications of the HDCARP include snow plowing, salt spreading, street cleaning, and waste collection. In this study, we explore two variants of the HDCARP. The key difference between these variants lies in the consideration of precedence relations between classes within routes. We propose MILP formulations and matheuristics for both HDCARP variants. The MILP formulations enable us to find optimal solutions for small-scale instances and evaluate the quality of matheuristics. Our matheuristics are based on decomposing the problem into multiple sub-problems, resulting in faster running time for large-scale instances. We conduct extensive computational experiments to assess the performance of these approaches and present our findings.

1 - Shapley value analysis for revealing molecular signature in Raman Spectra

Marco Piazza, Enza Messina, Mauro Passacantando

Raman Spectroscopy is a technique based on the inelastic scattering of a monochromatic light beam used to observe low-frequency modes in a target molecular system. The scattering pattern can be viewed as a sort of "fingerprint" that encodes information about the chemical composition of a given target, including presence, concentrations, and interactions among molecules. Recently, Raman spectra of biofluids have been used for medical diagnosis, and Machine Learning and Deep Learning models have been proposed for the development of noninvasive tests for early diagnosis. However, the lack of interpretability of these models makes decoding and interpreting the Raman spectral fingerprint a challenging task. In this work, we explore the application of eXplainable Artificial Intelligence (XAI) methods to extract explanations aimed at the possible identification of new biomarkers. Among the possible approaches, feature attribution methods seem to be the most promising for analyzing spectroscopic data, and we will focus our attention on Shapley value methods based on cooperative game theory. The computational results of a comparative analysis will be presented and discussed.

2 - Unboxing Tree ensembles for interpretability: A hierarchical visualization tool and a multivariate optimal rebuilt tree

Giulia Di Teodoro, Marta Monaci, Laura Palagi

The interpretability of models has become a crucial issue in Machine Learning because of algorithmic decisions' growing impact on real-world applications. Tree ensemble methods, such as Random Forests or XgBoost, are powerful learning tools for classification tasks. However, while combining multiple trees may provide higher prediction quality than a single one, it sacrifices the interpretability property resulting in "black-box" models. In light of this, we aim to develop an interpretable representation of a tree-ensemble model that can provide valuable insights into its behavior. First, given a target tree-ensemble model, we develop a hierarchical visualization tool based on a heatmap representation of the forest's feature use, considering the frequency of a feature and the level at which it is selected as an indicator of importance. Next, we propose a mixed-integer linear programming (MILP) formulation for constructing a single optimal multivariate tree that accurately mimics the target model predictions. The goal is to provide an interpretable surrogate model based on oblique hyperplane splits, which uses only the most relevant features according to the defined forest's importance indicators. The MILP model includes a penalty on feature selection based on their frequency in the forest to further induce sparsity of the splits. The natural formulation has been strengthened to improve the computational performance of mixed-integer software.

3 - Feature Selection for Regression Neural Network using Mathematical Programming

Georgios Liapis, Sophia Tsoka, Lazaros Papageorgiou

In recent years, a growing body of literature has focused on training sparse deep neural networks or refining already trained ones towards making them sparser. The strategic reduction of complexity of the network has shown to effectively mitigate overfitting, improve overall generalisation performance and enhance explainability. This work introduces a feature selection approach tailored for regression tasks in trained neural networks, utilising Rectified Linear Unit (ReLU) activation functions. The methodology simplifies the network by identifying and retaining only the most important features for the input layer.

This problem is mathematically formulated as a Mixed-Integer Linear Programming (MILP) model. This model formulates the ReLU operator with binary variables, enabling the application of big-M constraints, while limiting the number of active features. The objective of the model is to identify and eliminate the features that do not significantly contribute to the prediction quality of the neural network, so that it can be re-trained using only the rest of them. A binning strategy is employed on the output variable in order to assess the importance of features across the entire spectrum of the output. Through a number of real-world datasets, it is demonstrated that the complexity of the network is reduced, while maintaining good predictive performance.

4 - Selecting variables in additive models as linear or nonlinear terms

Vanessa Guerrero, Manuel Navarro García, Maria Durban, Arturo del Cerro

In an era when the decision-making process is often based on the analysis of complex and evolving data, it is crucial to have systems which allow us to incorporate human knowledge and provide valuable support to the decision maker. In this work, statistical modelling and mathematical optimization paradigms merge to address the problem of feature selection in additive models while deciding if the variables are linear or nonlinearly related with the outcome. We assume that the smooth functions involved in the additive model are defined through a reduced-rank basis (B-splines) and fitted via a penalized splines approach (P-splines). A mixed-integer quadratic optimization model is proposed to address the variable selection model and a matheuristic approach, based on the Large Neighborhood Search paradigm, is developed to solve larger instances. The proposed methodology is tested in both simulated and real datasets and it is shown to be competitive against other approaches in the literature.

1 - A new centrality measure for misinformation diffusion

Safiye Şeyma Kaya Gezmiş, Zeynep Aksin, Barış Yıldız

Social networks offer the capability to spread inspiring ideas and adapt innovations at unprecedented speed and convenience. Although such an information spreading capability is invaluable, social networks can also rapidly disseminate misinformation to a large number of people, with dire consequences for impacted individuals and societies. In this study, we focus on the spread of a specific type of misinformation: acute rumors (AR), which we define as misinformation with the potential to quickly spread in the network and mobilize individuals to take harmful actions. We present a new diffusion model for AR, which extends the classical linear threshold model by considering the base idea of the individuals regarding the topic of the rumor and the emotional impact its content creates on them. Based on this diffusion model, we propose a new centrality measure that can accurately detect individuals with a high potential to enhance the spread of AR. In a comprehensive numerical study, we evaluate the performance of our proposed centrality measure by comparing it to existing traditional centrality measures in the literature. Our results attest to the superior performance of our centrality measure not only in terms of detecting the individuals with the highest potential to increase the reach of AR but also in finding the correct ranking among the individuals in the network regarding their potential to contribute significantly to the dissemination of acute rumors.

2 - Limited memory bundle DC algorithm for sparse pairwise kernel learning

Napsu Karmita, Kaisa Joki, Antti Airola, Tapio Pahikkala

Pairwise learning is a specialized form of supervised learning that focuses on predicting outcomes for pairs of objects. Data with pairwise observations naturally arise, for instance, in recommender systems, information retrieval, drug-target interaction (DTI) prediction, and link prediction in social networks. Here, we formulate the pairwise learning problem as a difference of convex (DC) optimization problem using the Kronecker product kernel, L1- and L0-regularizations, and various possible nonsmooth loss functions. Our aim is to create an efficient learning algorithm, SparsePKL, that produces accurate predictions with the desired sparsity level. In particular, we aim to solve the realistic form of the DTI problem called zero-shot learning, which corresponds to predicting labels for drug-target pairs where neither the drug nor the target is encountered during the training phase. In addition, we propose a novel limited memory bundle DC algorithm (LMB-DCA) for general large-scale nonsmooth DC optimization and apply it as an underlying solver in the SparsePKL. The performance of the SparsePKL algorithm is studied in seven real-world drug-target interaction data, and the results are compared with those of the state-of-the-art methods in pairwise learning. Further, we evaluate the LMB-DCA as a standalone optimization method by comparing it with the well-known DCA.

3 - Beyond the Pearson's correlation coefficient: a general-purpose measure for quantifying the dependency between random variables

Rob van der Mei, Guus Berkelmans, Joris Pries, Sandjai Bhulai

When analyzing a data set, typical questions are: 'Do underlying relationships exist?', 'Are some variables redundant?', and 'Is some target variable Y highly or weakly dependent on variable X?'. Interestingly, despite the evident need for a general-purpose measure of dependency between RV's, common practice of data analysis is that most data analysts use the Pearson correlation coefficient (PCC) to quantify dependence between RV's, while it is well-recognized that the PCC is essentially a measure for linear dependency only. Although many attempts have been made to define more generic dependency measures, there is yet no consensus on a standard, general-purpose dependency function. In this talk, we will discuss and revise the list of desired properties and propose a new general-purpose dependency function provides data analysts a powerful means to quantify the level of dependence between variables.

4 - Data envelopment analysis with machine learning in healthcare efficiency: a prematurity study

Fernando Marins, Elias Carlos Aguirre Rodríguez, Elen Yanina Aguirre Rodríguez, Diego Eduardo Quagliato Scarelli Cava, Luiz Fernando Costa Nascimento, Aneirson Francisco da Silva, Anderson Rodrigo de Queiroz

Prematurity (birth before the 37th week of gestation) is a leading cause of neonatal mortality and heightened complications in newborns. In Brazil, the annual cost of premature births is approximately R\$8 billion, with newborns spending an average of 51 days in intensive care, totalling a yearly cost exceeding R\$15 billion, so improving the health system for mothers and premature births is essential. Data Envelopment Analysis (DEA) is a vital tool to evaluate healthcare system efficiency across territories, but measuring efficiency over time requires re-implementing DEA models. Consequently, Machine Learning (ML) emerges as a viable solution for predicting efficiency scores through supervised learning. Therefore, this study integrates DEA, specifically the Constant Returns to Scale (CRS) model with input orientation, with ML techniques to develop a predictive model for healthcare system efficiency based on prematurity and incorporating indicators such as the number of physicians, beds, healthcare establishments, and per capita health expenditure (R\$) in Brazil's microregions. The DEA analysis assesses each microregion's readiness to care for premature newborns, providing inverted efficiency indicators where Decision-Making Units (DMUs) with values near or equal to one suggest lower performance. This approach enables determining

efficiency for new DMUs through ML, based on DEA indicators and results, while identifying sectors needing improvement in the health-care system.

1 - Bi-objective Algorithms for a Vehicle Replacement Problem including Budget Constraints and CO2 Emissions Minimization

Giulia Caselli, Joseph Hartman, Manuel Iori, Carlo Alberto Magni, Giorgio Zucchi

The transportation sector, encompassing road (the primary source), sea, and air transport, accounts for 14% of global emissions over the last decade and around 25% of total greenhouse gas emissions in the European Union. This underscores the imperative for companies to prioritize transitioning to cleaner and greener modes of transport in their medium- to long-term vehicle investment plans. In this work, we address an original vehicle replacement problem with environmental concerns. A keep-or-replace decision must be made for every asset of the fleet in every time period while meeting budget constraints to minimize total discounted costs and CO2 emissions. Multiple options for replacement are given for every family of assets in such a way that fuel-based vehicles may be replaced by, for instance, electric and hybrid vehicles. The problem is inspired by a real-world industrial application in Italy and, because of its generality, can be used to model a large variety of further applications. We provide a dynamic programming model and integer programming formulations for the problem. Then, we compare the formulations and propose different bi-objective approaches to solve the problem in practice.

2 - A new MILP model for the Simple Assembly Line Balancing Problem with Power Peak Minimization

Paolo Gianessi, Xavier Delorme

The constantly-increasing concern on environment and sustainability and the recent events which have pushed energy prices to alarming levels have led manufacturing systems to try to achieve higher standards of energy efficiency. This is the reason behind the growing interest of the research community in the study of optimization problems in production systems that deal with energy-related constraints and/or criteria. Among them is the Simple Assembly Line Balancing Problem with Power Peak Minimization (SALB3PM). The problem attempts to assign the tasks of a production process to the workstations of a paced straight machining line, and to determine their starting times so as to minimize the peak of the overall power consumption profile. This work focuses on the SALB3PM and proposes a new Mixed-Integer Linear Programming formulation in which a set of binary three-index variables models the core assignment and trigger decisions. We show that the proposed model outperforms the reference 01LP model on a benchmark instance set. We then test the model on new instances in which tasks have non constant power profiles and we propose some valid inequalities and preprocessing. Numerical results are presented and discussed.

3 - Stochastic facility location problem with outsourcing costs

Eduardo Moreno, Ivana Ljubic

Stochastic facility location problems with outsourcing costs (SFLPOC) optimize facility placement and customer assignment under demand uncertainty. Excess demand beyond a facility's capacity incurs outsourcing costs. This work addresses SFLPOC, aiming to minimize overall expected costs (installation, servicing, and outsourcing).

We model SFLPOC as a two-stage stochastic program. While prior work focused on specific assumptions or small scenario sets, we present methods suitable for general probability distributions. For discrete scenario sets, we improve upon classic Benders decomposition by exploiting the second-stage subproblem's structure.

To handle general distributions, we partition the probability space, enabling the computation of expected values with fewer scenarios. Coupled with Benders cuts, this provides an exact solution method for common distributions (e.g., Bernoulli, Gaussian).

Additionally, we introduce a compact formulation specifically for i.i.d. demand distributions, allowing us to solve even continuous distribution problems to optimality. Computational experiments on established benchmarks demonstrate that our compact formulation consistently finds optimal solutions, while the Benders approach provides strong solutions with proven optimality gaps for general distributions, outperforming sample average approximations.

4 - Locally Stable Roommate Problem

Elise Vandomme, Marie Baratto, Yves Crama

In 1962, Gale and Shapley initiated the study of stable matching problems, introducing the Stable Marriage Problem (SMP). The aim is to match men and women based on their preferences for all members of the opposite gender. A matching is deemed stable if there are no pairs of unmatched individuals who prefer each other to their partners in the matching. We say that there are no blocking pairs. A natural generalization of SMP is to consider non-bipartite models. For instance, consider a set of n individuals where each one ranks all the others in order of preference. In this context, a matching can be assimilated to pairing individuals to share living spaces, leading to the formulation of the Stable Roommate Problem (SRP). While there always exists a stable matching in SMP, it is not the case in some instances of SRP. However, Irving provided a polynomial algorithm that, for any instance of SRP, determines whether a stable matching exists or not. If it exists, it produces one. We focus on a different definition of stability, namely local stability, recently introduced in the context of kidney exchange programs (KEPs). The decision problem's complexity for non-empty locally stable exchanges remains open. When the exchange is a matching, this is equivalent to a local version of SRP. Here, a matching achieves local stability if no blocking pairs intersect with it. In this talk, we explore the trade-offs between global and local stability and discuss the complexity of local SRP.

1 - An Introduction to PyPSA: Exploring Open-Source, High-Resolution Energy Planning

Elisabeth Zeyen, Iegor Riepin

PyPSA (Python for Power System Analysis) is an open-source toolbox to simulate and optimise modern power and energy systems. It encompasses various functionalities, such as conventional generators and links with unit commitment, variable wind and solar generation, storage units, coupling to other energy sectors, and mixed alternating and direct current networks. PyPSA is graph-based and designed to scale well with large networks and long time series.

PyPSA is used in several projects, such as PyPSA-Eur, which focuses on the European energy system. PyPSA-Eur automates the creation of highly detailed models of the European transmission networks of several energy carriers, incorporating renewable energy potentials, conventional power plants, and demand data across different sectors. This enables researchers and policymakers to conduct extensive analyses of network expansion, storage needs, and sector coupling strategies essential for achieving carbon neutrality.

This presentation will explore the functionalities, applications, and recent advancements of PyPSA and PyPSA-Eur. We will explore case studies demonstrating their use in optimising energy systems for cost-effectiveness and sustainability. Attendees will gain insight into the potential uses of these software tools in energy system planning and operational research.

2 - GAMSPy: The Best of Both Worlds - Integrating Python and GAMS

Justine Broihan

Optimization applications combine technology and expertise from many different areas, including model-building, algorithms, and data-handling. Often, the gathering, pre/post-processing, and visualization of the data is done by a diverse organization-spanning group that shares a common bond: their skill in and appreciation for Python and the vast array of available packages it provides. For this reason, GAMS offers a new comfortable way to integrate with Python on the data-handling and modeling side. In this talk, we will explore the benefits of our Python library GAMSPy.

3 - Convenient and Efficient Implementation of Analytic Python Apps with Xpress Insight and Workbench

Alexander Biele

In this talk we aim to illustrate the efficient reduction of development time and enhancement of the developer experience for fully fledged analytic Python applications, utilizing FICO Xpress Workbench and Xpress Insight. Our discussion spans across all stages of the development cycle, encompassing model implementation, scenario analysis, and the crucial feedback loop closure with business users.

Our initial focus involves showcasing the seamless deployment of an analytic Python model, transforming it into a fully operational application within Xpress Insight. Then we demonstrate the latest enhancements for Python language support in our IDE Xpress Workbench. We will showcase how advanced debugging features lead to an improved and integrated development experience. Beyond local debugging, we will spotlight remote debugging capabilities tailored for scenarios executed in Xpress Insight. This becomes particularly significant as production data might be inaccessible on a developer's laptop due to security considerations.

4 - Matrix-friendly modeling with gurobipy

Robert Luce

Gurobipy makes it very easy to build optimization models that are naturally formulated with multi-dimensional constraints. In particular you can use familiar concepts from NumPy like dimensions, shape, vectorization and broadcasting in combination with gurobipy's matrix-friendly objects to construct your optimization model. In this talk we will walk you through the functionality, discuss performance aspects, and present best practice code patterns.

1 - How should volunteers be dispatched to out-of-hospital cardiac arrests?

Caroline Jagtenberg

Survival for out-of-hospital cardiac arrest (OHCA) can be significantly improved through bystander efforts. To shorten the time to good-quality cardiopulmonary resuscitation, some emergency call centers use mobile phone technology to rapidly locate and alert nearby trained volunteers. Several such community first responder (CFR) systems are active worldwide, for example GoodSAM, which operates in the UK, Australia and New Zealand.

GoodSAM sends so-called phased alerts: they notify increasingly many volunteers with built-in time delays. The policy that defines these delays affects (1) response times - which have a direct relation to survival - (2) CFR workload and (3) the number of redundant CFR arrivals. We start by comparing policies through Monte Carlo Simulation, in which we use bootstrapped values from historical GoodSAM responses, estimating the three KPIs above. CFR app managers can use those results to identify a policy that displays a desirable trade-off between the performance measures.

We continue by using machine learning to predict the best policy to use, given where the volunteers are observed in relation to the patient. We do this by formulating the problem as a multiclass classification problem, for which we train a tree on the results from the simulations above. We compare the performance of the tree against a policy designed by dynamic programming. Finally, we look into optimal trees which go beyond the heuristic nature of machine learning algorithms.

2 - Unlocking the Value of Extensive Data: Estimating spatial cardiac arrest risk to guide resource allocation decisions

Derya Demirtas, Robin Buter, Remy Stieglis, Hans van Schuppen

Out-of-hospital cardiac arrest (OHCA) is a significant public health problem with notably low survival rates. Early defibrillation is crucial for survival, highlighting the importance of nearby automated external defibrillators (AEDs). Current AED placement strategies often rely on historical OHCA data, which are limited in availability. Publicly available demographic/socioeconomic data are often easily available and shown to have correlations with OHCA risk. This study aims to 1) estimate spatial cardiac arrest risk using demographic/socioeconomic data alone 2) compare AED location models based solely on estimated risk with those incorporating historical OHCA data to inform demand. Machine learning techniques were applied to a comprehensive dataset spanning multiple municipalities. Predicted OHCA incidence of each district were used to optimize AED locations, alongside AED optimization models that used smoothed out historical cardiac arrest data as demand. Results on several municipalities underscore the value of an OHCA registry. Nonetheless, in its absence, machine learning models leveraging demographic and socioeconomic data offer a viable means to substantially enhance coverage.

3 - Data-driven optimization of wildfire resource deployment

Mostafa Rezaei, Yasser Zeinali, Ilbin Lee

Wildfires impose significant health, environmental, and social costs annually. This paper presents the development of a predictive and prescriptive framework for deploying three wildfire suppression resources: air tankers, helicopters, and firefighters. Leveraging fifteen years of historical data on wildfires in Alberta, Canada, we initially train machine learning models to predict both the daily number of fire occurrences and the required hours of suppression resources. Subsequently, we utilize the forecasts in an optimization procedure to ascertain the necessary number of suppression resources at various bases, aiming to minimize response time. The optimization procedure employs a queueing model to compute the response time probabilities for fires. Given resource shortages, the historical level of resource usage serves as a lower bound for the required resources. To address this, we incorporate survival analysis techniques into the forecasting models to account for data censoring. Our results can guide wildfire managers and decision-makers in enhancing the acquisition and allocation of fire suppression resources.

4 - Manufacturing Process Optimisation and Predictive Analytics: Leveraging Data to Minimise Giveaway in Cheese Production

Giwa Reagan Iziomo, Ozren Despic, Jiabin Luo, Viktor Pekar, Eliseo Vilalta-Perdomo, Tim Fisher

This study addresses the challenge of high giveaway in Soft Cheese (British Brie) manufacturing, aiming to standardise weights and increase yields. Soft Cheese is produced by placing wet curds into moulds to form specific shapes and weights, which cannot be modified post-formation. Initial hypotheses suggested that weight variations were due to differences in properties between the outer and inner cheeses within a mould, caused by design issues. The project employed optimisation techniques and designed experiments to collect intricate data from the production process. This data aimed to capture variations in causes (production steps) and effects (weight inconsistencies), generating analytical datasets which were examined using descriptive visualisations, hypothesis testing, and predictive analytics, including machine learning. Causal inference methods were applied to quantify the impact of different factors on weight variations. Key recommendations included the introduction of a standardised mould filling system and improved mould trays to address intra-tray effects. For inter-tray effects, mainly linked to changing curd properties during production, a software-driven solution was implemented to automatically adjust for these changes. These measures reduced giveaways from 21% to 9%, resulting in substantial savings. This interdisciplinary initiative showcases the integration of optimisation techniques and predictive analytics to solve a critical issue in food manufacturing.

1 - Differentiating Nonsmooth Solutions to Parametric Monotone Inclusion Problems

Antonio Silveti-Falls

Understanding the differentiability and regularity of the solution to a monotone inclusion problem is an important question with consequences for convex optimization, machine learning, signal processing, and beyond. Past attempts have been made either under very restrictive assumptions that ensure the solution is continuously differentiable or using mathematical tools that are incompatible with automatic differentiation. In this talk, we discuss how to leverage path differentiability and a recent result on nonsmooth implicit differentiation calculus to give sufficient conditions ensuring that the solution to a monotone inclusion problem will be path differentiable and provide formulas for computing its generalized gradient. Our approach is fully compatible with automatic differentiation and comes with assumptions which are easy to check, roughly speaking: semialgebraicity and strong monotonicity. We illustrate the scope of our results by considering three fundamental composite problem settings: strongly convex problems, dual solutions to convex minimization problems and primal-dual solutions to min-max problems.

2 - Inexact Restoration trust-region algorithm with random models for unconstrained noisy optimization

Simone Rebegoldi, Benedetta Morini

We consider unconstrained smooth optimization problems where the evaluation of both the objective function and its gradient is subject to errors. Particularly, we assume that the function and gradient estimates are random and sufficient accuracy in the estimates can be guaranteed with sufficiently high probability. Following the popular Inexact Restoration framework, we reformulate the original problem as a constrained problem, where the constraint $h(y)=0$ represents the ideal case in which the function and the gradient are evaluated exactly, being y the noise level and h a non-negative function whose value is related to the accuracy that the estimates can achieve in probability. We show that our problem setting is viable for well-known optimization problems and then design a new trust-region algorithm that employs first-order random models. We analyze the properties of the algorithm and provide the expected number of iterations required to reach an approximate first-order optimality point. We also validate our proposed algorithm on a collection of least-squares problems, showing that it achieves comparable or lower noiseless values on average with respect to a state-of-the-art competitor.

3 - Conservation laws for gradient flows

Sibylle Marcotte

Understanding the geometric properties of gradient descent dynamics is a key ingredient in deciphering the recent success of very large machine learning models. A striking observation is that trained over-parameterized models retain some properties of the optimization initialization. This "implicit bias" is believed to be responsible for some favorable properties of the trained models and could explain their good generalization properties. In this talk, I will first rigorously expose the definition and basic properties of "conservation laws", that define quantities conserved during gradient flows of a given model (e.g. of a ReLU network with a given architecture) with any training data and any loss. Then I will explain how to find the exact number of independent conservation laws by performing finite-dimensional algebraic manipulations. In the specific case of linear and ReLU networks, this procedure recovers the conservation laws known in the literature and shows that there are no other laws.

4 - (Automatic) Iterative Differentiation: some old (& new) results

Samuel Vaïter

In this presentation, I will introduce some convergence results concerning the automatic differentiation of iterative algorithms, i.e., differentiating through the iterations, whether they are "smooth" or not. While the asymptotics of smooth problems are well understood (Gilbert 1992, Beck 1994), mainly thanks to the use of a fixed point theorem, the non-smooth case presents more difficulties. I will show how the framework of conservative Jacobians can achieve such results. I will also illustrate a strategy to adopt when the operator is not contracting, taking the differentiation of the Sinkhorn-Knopp algorithm as motivation. Finally, I will discuss one-shot differentiation, a method that combines the simplicity of automatic differentiation with the performance of implicit differentiation (in some cases). This approach, particularly suitable for fast algorithms, will be illustrated through superlinear optimization methods and bi-level optimization scenarios. Work in collaboration with Jérôme Bolte (Toulouse School of Economics) and Edouard Pauwels (Toulouse School of Economics).

1 - Fuzzy logic based approach for optimal control of dynamical systems under uncertainty

Svetlana Asmuss, Natalja Budkina

The aim of this research is to develop a fuzzy logic based technique for optimal control of dynamical systems under vague conditions which allows, among other, to solve optimal trajectory planning and contour modelling problems with uncertainty in location constraints. The goal is to find a control law that will drive the output trajectory in such a way that vague constraints are satisfied in the fuzzy logic sense. In order to adapt methods for control under specific types of uncertainty, we develop and apply fuzzy logic based mathematical tools such as fuzzy optimization, fuzzy metrics, etc. Fuzzy relations of a special design are used to incorporate uncertainty of constraints into the classical setting of the optimal control problem under consideration. The proposed approach is illustrated with examples, the numerical part of the analysis of which is reduced to quadratic programming.

2 - Measurized Markov Decision Processes

Alba V Olivares-Nadal

In this talk, we introduce a framework that facilitates the analysis of discounted infinite horizon Markov Decision Processes (MDPs) by visualizing them as deterministic processes where the states are probability measures on the original state space and the actions are stochastic kernels on the original action space. More specifically, we provide a simple general algebraic approach to lifting any MDP to this space of measures; we call this to measurize the original stochastic MDP. We show that measurized MDPs are in fact a generalization of stochastic MDPs, thus the measurized framework can be deployed without loss of fidelity. Lifting an MDP can be convenient because the measurized framework enables constraints and value function approximations that are not easily available from the standard MDP setting. For instance, one could add restrictions or build approximations based on moments, quantiles, risk measures...etc. In addition, measurized MDPs are deterministic and are particularly beneficial when managing large populations. A reason is that high-dimensional weakly coupled MDPs can be reduced into a unidimensional MDP in the space of distributions when the state-components are independent and identically distributed. This implies that solving the measurized problem only requires aggregated information, eliminating the impractical assumption of constantly having detailed and updated information for each component in high-dimensional contexts.

3 - Regularity in optimal control and applications

Vladimir Veliov

The talk is devoted to an extension of the property of strong metric sub-regularity of mappings. We focus on the so-called optimality mapping associated with the system of first order necessary optimality conditions for ODE optimal control problems. Problems that satisfy the Legendre-Clebsch condition and affine optimal control problems will be considered separately.

Two applications will be presented: (i) existence of Lipschitz continuous optimal feedback control; (ii) convergence with error estimates of discretization and Newton-like methods for optimal control.

4 - Optimal control of a generalized Fokker-Planck equation

Stefana-Lucia Anita

Our talk concerns an optimal control problem (P) related to a generalized Fokker-Planck (FP) equation. First we establish some properties of the solutions to the generalized FP equation using a semigroup approach in an appropriate Sobolev space. Problem (P) is proven to be deeply related to a stochastic optimal control problem (PS) for a McKean-Vlasov equation. We prove next the existence of an optimal control for the deterministic problem (P) and the existence of an optimal control for an approximating optimal control problem (Ph) related to a backward Euler approximation of the generalized FP equation (with a constant discretization step h). Finally, we show that under additional hypotheses "(Ph) converges to (P)" in a certain sense. First order necessary optimality conditions for (Ph) are derived as well.

Invited session

Chair: *Frauke Liers*

Chair: *Marc Goerigk*

1 - Robust Spare Parts Inventory Management with Emergency Shipment

Zhao Kang, Ahmadreza Marandi, Rob Basten, Ton de Kok, Joan Stip

We develop an Adaptive Robust Optimization (ARO) model for managing spare parts inventory in the early stages of a product's life cycle. This model takes into account demand uncertainty and emergency shipments. To obtain the exact solutions of the ARO model, we establish its equivalence to a deterministic counterpart. We prove that the deterministic counterpart can be decomposed into two subproblems. Based on this decomposition, we develop an efficient algorithm to obtain near-optimal solutions for thousands of stock-keeping units.

We conduct a case study at ASML, highlighting the practical implications of our ARO model for spare parts inventory in the semiconductor industry. Our results show that the ARO solution is more cost-effective than that of the conventional stochastic optimization model. Additionally, the adaptability of the ARO model to parameter variations, such as the emergency shipment time and cost, demonstrates its superiority in providing flexible and economically viable solutions.

2 - Multistage Sales and Production

Dominic Keehan, Andy Philpott, Andrew J Mason

We study a multistage sales and production problem. At each stage a market price is observed, sales decisions are made, and resources are available for a production decision which yields products to be sold at later stages. The prices of each product evolve randomly. To address model ambiguity, we study two distributional robustifications of the sample average version of this problem. The model is applied to a problem arising in New Zealand's dairy industry. We first compare the out-of-sample performance of the sample average policy to that of a model predictive control policy which is shown to be distributionally robust with an ambiguity set of distributions with matched means. We then compare this with a distributional robustification using discrete Wasserstein distance-based ambiguity sets. The models are solved using stochastic dual dynamic programming in SDDP.jl.

3 - Open Problems in Robust Combinatorial Optimization

Marc Goerigk, Michael Hartisch

Robust combinatorial optimization has come a long way over the last 25 years. While many variants of decision criteria and uncertainty sets have been proposed, some cornerstones have emerged. These are min-max, min-max regret, two-stage, and recoverable robust problems with discrete, interval, continuous budgeted, and discrete budgeted uncertainty. In this talk, I take stock of the current state-of-the-art in these areas and point out the challenges that we face. This includes a list of promising open problems that I encourage the audience to consider.

4 - Computationally Efficient Data-Driven Distributional Robustness Over Time

Frauke Liers, Kevin-Martin Aigner, Andreas Bärmann, Kristin Braun, Sebastian Pokutta, Kartikey Sharma

Stochastic Optimization (SO) typically requires knowledge about the probability distribution of uncertain parameters. As the latter is often unknown, Distributionally Robust Optimization (DRO) provides a strong alternative that determines the best guaranteed solution over a

set of distributions (ambiguity set). We present an approach for DRO over time that uses online learning and scenario observations arriving as a data stream to learn more about the uncertainty. Our robust solutions adapt over time and reduce the cost of protection with shrinking ambiguity. For various kinds of ambiguity sets, the robust solutions converge to the SO solution. Our algorithm achieves the optimization and learning goals without solving the DRO problem exactly at any step. We also provide a regret bound for the quality of the online strategy and also discuss how to perform a scenario reduction with approximation guarantee. We illustrate the effectiveness of our procedure by numerical experiments from popular benchmark libraries and give practical examples stemming from telecommunications and routing. Our algorithm is able to solve the DRO over time problem significantly faster than standard reformulations.

This talk is based on joint work with K. Aigner, A. Bärmann, K. Braun, S. Pokutta, O. Schneider, K. Sharma, S. Tschuppik. Parts of the talk are published in *INFORMS J Optimization*, 2023.

1 - Resilience enhancement of distributions networks with robust optimal sizing and location under uncertainty and random contingencies

Pascal Quach, Yiping Fang, Anne Barros

The resilience of power systems is challenged by increasingly frequent and severe environmental events. Anticipation of threats and vulnerabilities is crucial to ensure adequate response and recovery from extreme events. In this context, the deployment of local generation can help absorb the impact of system disturbances. Size and location of distributed energy resources are critical factors in determining their economic and technical viability. In this paper, we develop robust and distributionally robust optimization models among others, under load and supply uncertainty, and random contingencies. An illustrative case study is presented to demonstrate the models' performance on a benchmark distribution network with synthetic data combining a variety of representative days and failure scenarios in order to explore the trade-offs between reliability, costs, and resilience. System performance assessed under in-sample and out-sample scenarios constitute the resilience metrics.

2 - Polynomial-time algorithms to compute violation in the robust vehicle routing problem with time windows and budget uncertainty

Igor Malheiros, Michael Poss, Artur Pessoa, Anand Subramanian

This research focuses on the robust vehicle routing problem with time windows (VRPTW) under uncertain travel times. More specifically, we assume all travel times belong to a known budget uncertainty set. To solve large-scale instances, one often resorts to local search algorithms. These algorithms involve checking whether a route is feasible regarding the time window; if it is not, evaluate its infeasibility. Our goal is to study the computation of the infeasibility of the robust VRPTW with budget uncertainty for two classical cases of functions. We prove that the computation of both cases is polynomially solvable by providing dynamic programming algorithms to solve them.

3 - A two-stage stochastic programming approach for an electric fleet composition and mix vehicle routing problem.

Paolo Beatrici, Francesca Maggioni, Sebastian Birolini, Paolo Malighetti

In this talk we consider a fleet composition and delivery routing problem, performed by a heterogeneous fleet of both conventional and electric vehicles under uncertain demand. Multi-trips for recharging operations of the electric vehicles to the central depot are considered. The problem is modeled as a two-stage stochastic mixed integer program where the first stage decisions are related to the selection of the vehicles which compose the fleet while second stage decisions concern the routing to satisfy the uncertain customer demand. The aim is the minimization of total operation costs due to the initial acquisition of fleet components, the travel time of each vehicle and an extra penalty cost in case of unserved customers. A tradeoff between cost and emissions is evaluated to analyze the impact of the selection of electric vehicles in the delivery fleet. Scenarios representing the stochasticity in customers' demand are generated through a kernel density estimation approach. Computational experiments are carried out on instances based on real data of a large Italian delivery company. The impact of stochasticity on demand is examined through stochastic measures. Some managerial insights are finally discussed.

4 - Preventive maintenance in fixed interval scheduling problems under endogenous uncertainty - a stochastic optimization approach and exact decomposition algorithm

Martin Branda

Fixed interval scheduling deals with the problem of assigning jobs with fixed processing intervals to available machines. We consider the problem where the finishing times are subject to random delays. We elaborate the problem with expected number of overlaps objective which penalizes the number of additional machines needed to process the jobs when the delays appear and some jobs cannot be processed by the assigned machines. We consider preventive maintenance operations which can improve machine reliability and positively influence the distribution of the random delays of the jobs assigned to the same machine. This leads to a two-stage stochastic optimization problem with endogenous uncertainty for which we propose an extended robust coloring reformulation. We design a Benders decomposition algorithm to solve larger instances to optimality and perform a numerical study on simulated instances.

to providing misleading information for personal gain. We investigate five fundamental objective functions in lot scheduling: (i) minimizing the completion time of the last job exiting the system, (ii) minimizing the total completion time, (iii) minimizing the total weighted completion time, (iv) minimizing the number of tardy orders, and (v) minimizing the total weighted number of tardy orders. Notably, we show that problems (i) to (iv) can be efficiently solved in polynomial time, while problem (v) is solvable in pseudo-polynomial time. Our research advances the understanding of decentralized scheduling, where agents' behavior and information gaps affect decision-making. It underscores the need to address real-world complexities in scheduling theory and provides insights for designing adaptable algorithms.

2 - Parallel axiomatizations of generalized weighted-egalitarian Shapley values

Hyungkyu Cheon, Dong Gu Choi

Joosten (1996) attempted to reconcile marginalism and egalitarianism by proposing the egalitarian Shapley values, which is a convex combination of the Shapley value and the equal division values. Abe and Nakada (2019) generalized the equal division values of egalitarian Shapley values to propose weighted-egalitarian Shapley values. Recently, Cheon and Choi (2024) introduced a new solution by generalizing the Shapley values to the weighted Shapley values within this weighted-egalitarian Shapley values framework. In this study, we further advance the generalization of TU-values. This research delineates the axiomatic properties of solutions resulting from the convex combination of four classes of TU-values. These classes include convex combinations of the weighted division values with weighted Shapley values, positively weighted Shapley values, random order values, and the Harsanyi set. This research has been influenced by the parallel axiomatization of Besner (2020). Besner (2020) axiomatized weighted, positively weighted, and multiweighted Shapley values, random order values, and the Harsanyi set, presenting the axiomatization of all individual classes as a single theorem for all classes. In our study as well, within the main theorem, the axiomatization of adjacent two classes differs by only one axiom, and the process of generalization of classes of solutions and weakening of corresponding axioms progresses in the same direction.

3 - For how long should bids be valid in a procurement auction?

Panos Lorentziadis

Bids in procurement auctions are typically required to remain valid for a certain period of time. If the underlying cost changes in time, as for example due to inflationary economic conditions or changes of the production input prices, the eventual profit when awarding takes place may be dramatically lower than anticipated. To address this risk, bidders can impose an upper bound constraint on the probability that the final mark-up stays below a pre-determined level. In this setting we derive the equilibrium bidding strategies when the cost change is realized continuously or in discrete steps. We determine the effect of the validity time to the expected bidder profit and show how bidders can profit if the risk is correctly managed. On the other hand, we demonstrate that the contracting authority always suffers for a prolonged validity time in terms of the expected procurement project cost and we develop methods to determine the optimal time within which bids are valid. We explore and compare methods of price adjustments which can partially or totally compensate against cost change. We conclude with a discussion of the findings and recommendations for both bidders and auctioneers on the efficient management of this kind of risk.

1 - Optimizing Charging Station Infrastructure Deployment: A Multi-Objective Stochastic Programming Approach

Büşra Alptekin, Sule Itir Satoglu

Electromobility plays a pivotal role in achieving Net Zero emissions targets globally, with transportation accounting for 15% of emissions, 72% of which stem from road transportation. However, the widespread adoption of electric vehicles (EVs) poses significant challenges. EV penetration and CS network establishment are intertwined, resembling a chicken-and-egg problem. If EV demand stagnates, CS utilization remains low, discouraging investment from charging point operators (CPOs). Conversely, inadequate CS infrastructure worsens user concerns like range anxiety, hindering electrification. While existing studies often focus on one-time CS location decisions, developing a well-distributed CS infrastructure requires a holistic approach in decision-making. To address this, our objective is to formulate a multi-period CS network deployment plan focused on the most frequented highways. We propose a multi-objective stochastic programming approach to optimize sustainability dimensions and identify new CS locations to augment the existing network. This model embraces the Triple Bottom Line (TBL) approach, considering economic, ecological, and social aspects from the perspectives of charging point operators (CPOs), government entities, and EV users, respectively. Factors such as location, charger quantity, load capacity, grid expansion needs, and energy source types—be they transformer upgrades or renewable installations—are assessed across various EV penetration scenarios.

2 - A Multicriteria and Multi-Objective Framework for In-House and Outsourced Technological Developments by Open Banking

Vinicius Dezem, Swati Sachan, Marcelo Macedo, Andre Longaray

Open Banking is an innovative data-sharing framework designed for data interoperability among diverse financial and non-financial organizations, operating within a country's regulatory confines. Interoperability works through the deployment of application programming interfaces (APIs), which enable a two-way exchange of banking data with customers' consent. This scenario is poised to reshape the decision-making process of financial institutions, necessitating the refinement of strategies to implement customer-centric business models and augment profitability through the exploration of novel revenue streams. Facing the complexity of the banking market it's paramount to structure the decision context considering the multiple stakeholders and variables involved. This research presents a case study on a retail bank where stakeholders encountered challenges in structuring action plans for digital transformation following the launch of Open Banking. It introduces a Hierarchical Multi-criteria Decision-Aid (H-MCDA) framework for engaging stakeholders at various levels and proposes a Multi-objective Optimization (MOO) approach to assess and compare the effectiveness of multiple strategic plans, which aligns with technological innovation, customer interests, and the bank's long-term goals. Our findings present a comparison between two strategic action plan scenarios: the bank's intrinsic in-house technological developments and the outsourcing of technical expertise.

3 - An Iterative Optimization Framework for Streamlining Crude Oil Scheduling in Refinery Operations

İrem Marttin, Özgür Kabak, Melike Kamuran Onat, Büşra Aydın, Ahmet Nomer, Oğuz Şüyyün

Refineries are complex industries that take crude oil then fractionate and crack it into valuable products. Feed continuity and quality are very crucial for the production, so the petroleum scheduling is a key step for a stable operation. This study aims to develop an optimization tool addressing operational limits encountered practical contexts to facilitate adept decision-making in crude oil scheduling. To this end, a scheduling model was devised, covering the unloading of crude oil received via pipeline to multiple storage tanks, intra-tank crude oil mixing, and charging the resultant mixture to the crude distillation unit. An event-based continuous-time Mixed Integer Linear Programming formulation was created to effectively navigate the intricacies of the scheduling problem. Given the nonlinear problem stemming from the

homogenous crude oil mixture in the tanks, an iterative solution approach was designed. This approach breaks down the problem into manageable sub-problems based on periods of constant tank compositions. The viability of the proposed model has been evaluated through empirical assessments conducted on real refinery cases. The findings revealed satisfactory results within a brief interval, especially given the industrial scale and complexity of the problem covering 4 tanks with around 10 crude oil types. In this regard, the model aims to notably shorten scheduling time while enhancing efficiency through steady operations facilitated by prompt decision-making.

Invited session

Chair: Stefano Cipolla

Chair: Jacek Gondzio

1 - Quantum relative entropy optimization

Hamza Fawzi

Many problems in quantum information are formulated as convex optimization problems involving the quantum relative entropy function. These problems cannot be directly expressed as semidefinite programs. In this talk I will discuss various tools to deal with such optimization problems. In particular, I will present a self-concordant barrier with optimal parameter for the quantum relative entropy cone. This barrier function can be used with interior-point schemes to solve convex optimization problems with the quantum relative entropy function. Based on joint work with James Saunderson (arXiv:2205.04581).

2 - Proximal-Stabilized Semidefinite Programming

Stefano Cipolla, Jacek Gondzio

In this talk, we will present a regularized version of the primal-dual Interior Point Method (IPM) for the solution of Semidefinite Programming Problems (SDPs). Leveraging on the proximal point method, a novel Proximal Stabilized Interior Point Method for SDP (PS-SDP-IPM) is introduced. The method is strongly supported by theoretical results concerning its convergence: the worst-case complexity result is established for the inner regularized IPM solver. Moreover, the new method demonstrates an increased robustness when dealing with problems characterized by ill-conditioning or linear dependence of the constraints. Extensive numerical experience is reported to illustrate the advantages of the proposed method when compared to the state-of-the-art solver.

3 - Efficient Quantum Relative Entropy Programming with SDP Preprocessing

Mehdi Karimi, Levent Tunçel

Optimization over the quantum relative entropy (QRE) cone has many applications in quantum information processing, for example, calculating the key rates for quantum key distribution (QKD) protocols. Recently, a new version of our convex optimization software package Domain-Driven Solver (DDS) was released with modified numerical approaches for solving QRE programming problems, potentially combined with many other convex function/set constraints. In this talk, we propose a preprocessing and two-phase approach for QRE programming to reduce the size and improve the conditioning of a given instance. Phase-I of this two-phase approach is a well-behaved convex optimization problem, such as minimizing a self-concordant barrier or an SDP. The reformulated QRE programming problem can be solved

more efficiently and faster by DDS or other optimization algorithms. We finish the talk by presenting numerical results of using DDS for solving many classes of problems, including calculating the QKD rate for different protocols.

Analysis of Stochastic Models I

Stream: Stochastic Modelling
Invited session

Chair: Cristian Pelizzari

1 - Interarrival Distribution of a Periodically-Observed Time-Homogeneous Poisson Process

Sheldon Jacobson, Zach Hornberger, Douglas King

Despite the prevalence of Poisson process modeling in social science, little research has explored how the periodic collection of data affects the applicability of this model. Our research studies how discretization impacts the Poisson process model's interarrival distribution and introduces the periodically-observed time-homogeneous Poisson process (PTPP) model as a viable alternative. The long-run behavior of the PTPP is quantified and compared to the analogous Poisson process. We show the PTPP consistently provides a good approximation of process outputs regardless of discretization, extending the capabilities of the traditional model. The applicability of the PTPP model is demonstrated through multiple case studies.

2 - The Clustered-State Markovian Arrival Process: A Framework for Dependent Recurrence and Mortality Modeling

Álvaro Díaz Pérez, Rosa Elvira Lillo Rodríguez, Pepa Ramírez-Cobo

The Clustered-State Markovian Arrival Process (CS-MAP) is introduced as an extension of the Markovian Arrival Process (MAP). This new model can be employed to model marked point processes with a finite mark space, but our focus lies in its application for modeling recurrent processes with terminal events, which are prevalent in the biomedical context where temporal sequences of recurrences are observed, preceded by the death of the patient. We present novel results regarding this stochastic process, including explicit expressions for the marginal and joint densities and for the moments and correlations of the inter-event times, as well as for the probability mass function of the number of recurrences before death. Furthermore, we provide an explicit expression for the likelihood function, incorporating right-censoring, which is common in survival analysis. Maximizing the log-likelihood function poses a challenge due to the large number of parameters in the model; however, we propose a heuristic approach for this purpose and we employ an appropriate local maximization algorithm. Additionally, we introduce some methods to enhance computational efficiency, such as a simplification of the likelihood function. Finally, we demonstrate the effectiveness of the proposed maximum likelihood approach using simulated data and apply it to model real data concerning patients with oncological diseases.

3 - Markov Chain Bootstrapping and Simulation for a Quadrivariate Stochastic Process in Energy Market Scenario Generation

Cristian Pelizzari, Enrico Angelelli, Paolo Falbo, Alessandra Ruffini

Research in energy markets often requires jointly considering multiple sources of uncertainty. Among all players in the energy markets, typical sources of profit uncertainty are supply costs, weather conditions, sale prices, and demand levels. Typically, these components are not independent of one another. Moreover, the dependencies are often

non-linear. In turn, this makes investment and management decisions and risk assessment complex. In the methodological field, an approach that has proven particularly effective in modelling linear and non-linear dependencies among multiple sources of uncertainty was advanced in Cerqueti et al. (2017). The method is based on the approximation of stochastic processes through Markov chains of order k , with k belonging to the set $1, 2, \dots$. The present work is concerned with modelling the quadrivariate stochastic process of natural gas price, electricity demand, electricity price, and solar radiation based on the method of in Cerqueti et al. (2017). The novel aspect of the present method compared to its previous applications consists in the management of the different temporal frequencies of the four components (gas prices have a daily frequency, while the others have an hourly frequency). The method, based on the choice of a few parameters compared to other methods, allows us to bootstrap and simulate the quadrivariate stochastic process. Statistical tests are applied to the generated scenarios to assess their goodness of fit.

Tools and algorithms for equilibrium detection

Stream: Interfaces Between Optimization, Hierarchical Problems and Equilibrium Detection with Applications
Invited session

Chair: Laura Rosa Maria Scrimali

1 - Quasi-variational inequalities and applications: new challenges on the constraints set-valued map

Domenico Scopelliti

In 1982, Chan and Pang introduced the quasi-variational inequality, that is, a Stampacchia variational inequality where the constraints set is subject to modifications depending on the considered point. Nowadays, it provides a broad unifying setting for the study of several mathematical problems and real-world applications. The classical way to get the existence of solutions consists of requiring that the constraints set-valued map is a self-map; in addition, suitable continuity assumptions and properties on its values are required. However, to deal with the challenges arising from the applications, sometimes it is needed to remove some of these requirements. With this spirit, the talk aims to discuss some recent developments on the topic.

2 - Computing quasi-perfect equilibria: from a characterization to a differentiable path-following method

Chuangyin Dang, Yiyin Cao

As a different paradigm from Selten's perfection for rationality on strategy perturbation, the concept of quasi-perfect equilibrium was formulated by van Damme through backward induction for finite extensive-form games with perfect recall. The admissibility of quasi-perfect equilibrium gains itself an advantage over Selten's perfect equilibrium. Nevertheless, the formulation provides insufficient information on how to find such an equilibrium so that its existence was derived from the existence of a normal-form proper equilibrium (sufficient but unnecessary). To address this issue, this paper develops with a separation technique an equivalent definition of quasi-perfect equilibrium through the introduction of epsilon-quasi-perfect equilibrium and establishes directly the existence of a quasi-perfect equilibrium. To demonstrate its computational effectiveness, we illustrate with simple examples how one can employ the definition to analytically find all the quasi-perfect equilibria. As a byproduct, we acquire an equivalent definition of sequential equilibrium. A further application of the definition leads to a differentiable path-following method to compute quasi-perfect equilibria.

3 - Heuristics and optimization-based methods for solving generalized Nash games: a comparison

Monica-Gabriela Cojocaru

In this paper, we introduce three heuristic algorithms to investigate their in solving Generalized Nash Equilibrium Problems (GNEP). The first is an evolutionary-inspired algorithm which utilizes competitive selection and (linear & nonlinear) regression to motivate generations of new points. The second involves stochastic gradient descent of the Shadow Point function across mass numbers of agents to find game solutions. Last but not least, we present an ANN-based model with intelligent agents who solve a GNEP. These algorithms are evaluated on 2 and 3 player games in 2 and 3 dimensions, with both linear and non-linear shared constraints. The success of these algorithms is discussed and compared vis-a-vis existing, optimization-based methods (such as VI/QVI and KKT-based methods), and the limitations of the algorithms are explored. Finally, we introduce two measures of performance for all the algorithms in terms of their capability of finding and describing the entire solution set of a GNEP.

This is joint work with: Benjamin Benteke, Kira Tarasuk, Nick Hoover and Mihai Nica (at U of Guelph)

4 - Equilibrium selection via approximation and penalization

Giancarlo Bigi

The selection of equilibria is a central issue in the management of multi-agent systems that can be partially controlled. Once the system has been modelled, the selection can be performed through an hierarchical program whose lower-level describes the equilibria of the system and the upper-level explicitly addresses the selection criterion through a suitable objective function. These hierarchical programs are simpler than more general bilevel structures as the lower-level problems are non-parametric with respect to the upper level variables. In order to tackle them, suitable approximated versions are introduced. On the one hand, the approximation does not perturb the original [exact] program too much and allows for some additional flexibility in the choice. On the other hand, it allows relying on suitable exact penalty schemes by recovering those regularity conditions that the original problems do not satisfy. These penalization approaches are addressed in detail and their convergence properties are established.

Lower-order composite optimization problems

Stream: Nonsmooth Optimization

Invited session

Chair: Xiaoqi Yang

Chair: Yaohua Hu

1 - Mix Sparse Optimization: Theory and Algorithm

Xiaoqi Yang

In this talk, we consider the ℓ_1 -norm regularization problem for mix sparse optimization and investigate its mathematical theory and algorithm. In the theoretical part, we first introduce the notions of sparse eigenvalue conditions, one of the weakest regularity conditions in the literature, and then establish the oracle property without any regularity condition and provide a recovery bound for the mix sparse optimization problem under the weak assumption of sparse eigenvalue condition. Moreover, an asymptotic analysis is provided to advance the understanding of the convergence of the ℓ_1 -norm regularization to the ℓ_1 -norm regularization. In the algorithmic part, we propose an iterative mix thresholding algorithm with continuation technique (IMTC) to solve the mix sparse optimization problem and present its global convergence theorem and linear convergence rate to a local minimum.

The significant advantage of the IMTC is that it has a closed-form expression and low storage requirement, and promotes the mix sparse structure of the solution. Numerical results on simulated data indicate that the IMTC has a strong promoting capability of the mix sparse structure and outperforms

2 - On Convergence of Iterative Thresholding Algorithms to Global Solution for Nonconvex Sparse Optimization

Yaohua Hu

Sparse optimization is a popular research topic in applied mathematics and optimization, and nonconvex sparse regularization problems have been extensively studied to ameliorate the statistical bias and enjoy robust sparsity promotion capability in vast applications. However, puzzled by the nonconvex and nonsmooth structure in nonconvex regularization problems, the convergence theory of their optimization algorithms is still far from completion: only the convergence to a stationary point was established in the literature, while there is still no theoretical evidence to guarantee the convergence to a global minimum or a true sparse solution. This talk aims to find an approximate global solution or true sparse solution of an under-determined linear system. We will propose two types of iterative thresholding algorithms with the continuation technique and the truncation technique respectively. We introduce a notion of limited shrinkage thresholding operator and apply it, together with the restricted isometry property, to show that the proposed algorithms converge to an approximate global solution or true sparse solution within a tolerance relevant to the noise level and the limited shrinkage magnitude. Applying the obtained results to nonconvex regularization problems with SCAD, MCP and L_p penalty and utilizing the recovery bound theory, we establish the convergence of their proximal gradient algorithms to an approximate global solution of nonconvex regularization problems.

3 - Avoiding strict saddle points of nonconvex regularized problems

Hao Wang

In this paper, we consider a class of non-convex and non-smooth sparse optimization problems, which encompass most existing non-convex sparsity-inducing terms. These problems, moreover, are probably non-lipschitz around sparse solutions. We propose a damped iterative reweighted ℓ_1 algorithm to solve these problems. The algorithm is guaranteed to converge only to local minimizers when randomly initialized. By deriving a second-order sufficient optimal condition under the non-degenerate assumption, we show that the strict saddle property is generic on these sparse optimization problems.

4 - An Inexact Projected Regularized Newton Method for Fused Zero-norms Regularization Problems

Yuqia Wu, Shaohua Pan, Xiaoqi Yang

In this talk, we are concerned with structured ℓ_1 -norms regularization problems, with a twice continuously differentiable loss function and a box constraint. This class of problems have a wide range of applications in statistics, machine learning and image processing. To the best of our knowledge, there is no effective algorithm in the literature for solving them. In this paper, we first obtain a polynomial-time algorithm to find a point in the proximal mapping of the fused ℓ_1 -norms with a box constraint based on dynamic programming principle. We then propose a hybrid algorithm of proximal gradient method and inexact projected regularized Newton method to solve structured ℓ_1 -norms regularization problems. The whole sequence generated by the algorithm is shown to be convergent by virtue of a non-degeneracy condition, a curvature condition and a Kurdyka-Lojasiewicz property. A superlinear convergence rate of the iterates is established under a locally H²-order error bound condition on a second-order stationary point set, without requiring the local optimality of the limit point. Finally, numerical results highlight the features of our considered model, and the superiority of our proposed algorithm.

Variational techniques in conic optimization and mean field games

Stream: Variational Analysis and Continuous Optimization
Invited session

Chair: Hector Ramirez

1 - A dual proximal-gradient approach for variational mean field games

Luis Briceño-Arias, Francisco José Silva Alvarez, Xianjin Yang

In this talk, we provide a new algorithm to approximate equilibria of variational mean field game systems (MFG) with local couplings. Under suitable conditions on the coupling function, the dual of the variational formulation of the MFG reduces to the minimization of the sum of a proper convex lower semicontinuous function and a differentiable convex function whose gradient satisfies a locally Lipschitz-type condition. In this context, we provide a generalization of the proximal-gradient (or forward-backward) splitting algorithm for tackling the dual problem. We prove the convergence of our method and derive a linear convergence rate when the differentiable function is locally strongly convex. We recover classical results in the case when the gradient of the differentiable function is globally Lipschitz continuous and an already known linear convergence rate when the function is globally strongly convex. Compared with some benchmark algorithms to solve these problems, our numerical tests show similar performances in terms of the number of iterations but an important gain in the required computational time.

2 - Real roots of real cubics and optimization

Manish Krishan Lal

The solution of the cubic equation has a century-long history; however, the usual presentation is geared towards applications in algebra and is somewhat inconvenient to use in optimization where frequently the main interest lies in real roots. In this note, we present the roots of the cubic in a form that makes them convenient to use and we also focus on information on the location of the real roots. Armed with this, we provide several applications in optimization where we compute Fenchel conjugates, proximal mappings, and projections.

This is a joint work with Heinz Bauschke and Shawn Wang.

3 - Extensions of Constant Rank Qualification Constraint Condition to Nonlinear Conic Programming

Hector Ramirez

We present new constraint qualification conditions for nonlinear conic programming that extend some of the constant rank-type conditions from nonlinear programming. Specifically, we propose a general and geometric approach, based on the study of the faces of the cone, for defining extensions of (relaxed) constant rank CQ and constant rank of subspace components condition to the conic context. We then compare these new conditions with some of the existing ones, including the nondegeneracy condition and Robinson's constraint qualification. The main advantage of the latter is that we are able to recast the strong second-order properties of the constant rank condition in a conic context. In particular, we obtain a second-order necessary optimality condition that is stronger than the classical one obtained under Robinson's constraint qualification, in the sense that it holds for every Lagrange multiplier, even though our condition is independent of Robinson's condition.

Tuesday, 14:30-16:00 - Room: 99 (building: 306)

Market Design 1

Stream: Market Design
Invited session

Chair: Aleksandrs Smilgins

1 - Successive incentives

Jens Leth Hougaard, Lars Østerdal, Juan D. Moreno-Ternero, Jens Gudmundsson

We study the design of optimal incentives in sequential processes. An agent initiates a value-creating sequential process through costly investment with random success. If unsuccessful, the process stops. If successful, a new agent thereafter faces a similar investment decision, and so forth. For any realization of the process, the total value is distributed among the agents using a reward rule. Such rules induce a game among the agents. The domain of the rules is very rich, yet we are able to show equilibrium existence. We characterize rules that yield the highest welfare created in equilibrium. We also characterize rules that yield the highest possible payoff for the initiator in equilibrium. A canonical class of rules are those in which an agent's reward (apart from the initiator) is affected by her own success but not the success or failures of others. Our findings show that such simple reward rules invoking short-run individual incentives are sufficient to meet our long-run systemic objectives.

2 - Saving Millions in Government Procurement Through Data Science and Market Design

Gabriel Weintraub, Marcelo Olivares, Daniela Saban, Piero Zanocco

Framework agreements (FAs) are procurement mechanisms used in private and public organizations by which a central procurement agency selects an assortment of products, typically through auctions, and then affiliated organizations can purchase from the selected assortment as needs arise. In Chile's central procurement agency (ChileCompra), FAs accounted for 23% of the procurement expenditures during 2018-19. However, descriptive analysis of purchase transaction data suggests that some FAs exhibited low levels of competition in the auctions used to select suppliers, which could potentially result in larger government expenditures. We collaborated with ChileCompra to redesign FAs to enhance competition introducing two important changes: (i) standardize the product catalogue using natural language processing algorithms; (ii) use this product standardization to induce more competition in the auctions to select of suppliers. These changes were implemented through an experimental design in the new Food FA to measure its impact, showing that inducing more intense competition in the auction stage reduced transaction prices by 8%. This pilot study ultimately led ChileCompra to implement a similar design in all of its FAs, and many of the improvements in the design of the FAs were included in the new regulation on government purchases. If we were to extrapolate the savings from our pilot re-design to all of these FAs, the total savings would amount to around US\$64 million in 2022.

3 - Bidding Strategies in Treasury Auctions

Sasa Pekec, Aleksandrs Smilgins

We use data from Danish and Swedish treasury auctions to analyze differences in bidding strategies and auction performance. Our analysis suggests that underreporting true valuations is more pronounced under discriminatory auction format than under uniform auction format. Analogously, underreporting of true demand quantity is more pronounced under discriminatory auction format than under uniform auction format. We find no significant difference in the expected government profit (relative to the market prices).

4 - Managing cascading network disruptions through optimal liability assignment

Jens Gudmundsson, Jens Leth Hougaard, Jay Sethuraman

Interconnected agents such as firms in a supply chain make simultaneous preparatory investments to increase chances of honouring their respective bilateral agreements. Failures cascade: if one fails their agreement, then so do all who follow in the chain. Thus, later agents' investments turn out to be pointless when there is an earlier failure. How losses are shared affects how agents invest to avoid the losses in the first place. In this way, a solution sets agent liabilities depending on the point of disruption and induces a supermodular investment game. We characterize all efficient solutions. These have the form that later agents—who are not directly liable for the loss chain—still shoulder some of the losses on the premise that they might have failed anyway. Moreover, we find that such indirect liabilities are necessary to avoid unbounded inefficiencies. Finally, we pinpoint one efficient solution with several desirable properties.

Pairwise comparisons and preference relations 2

Stream: Multiple Criteria Decision Analysis
Invited session

Chair: [Konrad Kułakowski](#)
Chair: [Matteo Brunelli](#)

1 - Pairwise Comparisons: Gauge Theoretical Aspects and Beyond

Jean-Pierre Magnot

I will review the existing links between pairwise comparisons and gauge theory in physics. These links already exist in portfolio management since 1999 but are highlighted only recently in pairwise comparisons, even if the mathematical structures are the same. After an introduction in which the necessary notions of connexion, holonomy and gauge are refreshed for the audience, I will give an in-depth description of the mathematical analogy between priority vectors with Yang-Mills fields, both in a deterministic and a stochastic way. In this picture, the notion of inconsistency indicator will have a plurality of natural meanings in terms of mathematical concepts. At the end of this short talk, I hope to have the time to discuss perspectives both for decision theory from physics, in particular with the controversial use of the theory of Lie groups but also with a minimal setting for pairwise comparisons in the framework of categories and also with quantization procedures, and for physics from decision theory, in particular with inconsistency reduction for scalar gauge fields (e.g. electromagnetic fields).

2 - A Simulation Analysis of Inconsistency Indices Values for Transitive Pairwise Comparison Matrices

Tomasz Starczewski, Paweł Tadeusz Kazibudzki

In the Analytic Hierarchy Process (AHP), a Consistency Index (CI) is used for detecting inconformity of a Pairwise Comparison Matrix (PCM). An original idea of T. Saaty is to compare value of CI with an average value of CI obtained for a large amount (e.g. 100,000) of random PCMs. The inventor of AHP idea has specified percentage thresholds for CI values, which should not be exceeded. However, as A.Z. Grzybowski has shown, very small number of random PCMs is even close to consistent in Saaty's sense (<https://doi.org/10.1016/j.eswa.2012.04.051>). Furthermore, according to Grzybowski's research, for PCMs of the size larger than 5, the probability of gaining PCM, that satisfies Saaty's consistency condition is close to 0. Hence, evaluation of the relationship between random PCMs and consistent PCMs is rather pointless. However, much higher percentage of randomly matrices are consistent, when transitive PCMs are taken into account. Moreover, PCMs given by real decision makers usually are transitive (despite of their inconsistency). Therefore, it was decided to investigate mostly that kind of PCMs. Thus, Monte Carlo

simulations for various CIs have been designed. The intent is to discuss the result of that examination, in particular certain characteristics of CIs distribution obtained for transitive PCMs. It is believed that, on the bases of these results, one can more credibly classify PCM as enough or not enough consistent.

3 - Performance Assessment of Sumo Wrestlers from Match Results as Incomplete Pairwise Comparison with Consideration of Match Time

Tsuneshi Obata, Shunsuke Shiraiishi

In most competitive sports, one of the main interests of the audience is to know who is truly strong. Various tournaments are held to determine the strongest champions, but the winners depend on the tournament regulations to no small degree. It is not always sure that the champion is the highest-performing team/player. The outcome of a competitive sports match, which wins, can be analogous to a pairwise comparison in decision-making. In many competitive professional sports leagues, all teams belonging to a league fight each other in a round-robin tournament, and the team with the most wins is honored as the champion. However, in Japan's professional sumo league, Ozumo, about 40 sumo wrestlers, rikishi, compete in a limited schedule of 15 days, so not all combinations of rikishi compete against each other. Using a method that handles incomplete pairwise comparisons, we propose a method for obtaining the values representing the actual performance of teams/players from the results of a semi-round-robin tournament such as Ozumo. For the construction of a pairwise comparison matrix, we consider match time. [U+3000] We also provide applications to the actual data of Ozumo.

4 - Extending AHP with Belief Degrees for Hesitant Evaluations

Ozge Sahin Zorluoglu, Özgür Kabak

The Analytic Hierarchy Process (AHP) method, developed by Thomas Saaty, is structured around pairwise comparisons to derive priority weights for decision criteria and alternatives. In this study, a new approach is presented by extending AHP method to be expressed in terms of belief degrees (BD). In AHP method decision maker (DM) may prefer to use different types of preference formats for each criteria to provide information. They may have hesitancy in expressing their evaluation by a single expression and they can use several linguistic expressions to evaluate alternatives. Therefore, hesitant fuzzy linguistics terms can be used. In this study we develop a new method to deal with problems where criteria weights are given as fuzzy preference relation and evaluations of DM is given as hesitant fuzzy sets. To aggregate different preference formats we transformed criteria weights and evaluations of DM to BD without any loss of information. Weighted Cumulative Belief Degree (WCBD) operator is employed for aggregation of alternative evaluations and criteria weights expressed with BD. First, a satisfaction level $s_r, q \in [0, \dots, 6]$ is determined for aggregations of evaluations by problem owner. By use of WCBD operator one can integrate two belief structures by considering t satisfaction level of problem owner. The developed method has been applied to various problems and has yielded satisfactory results.

■ TD-45

Tuesday, 14:30-16:00 - Room: 30 (building: 324)

Decision Support for Sustainable Operations

Stream: Decision Support Systems
Invited session

Chair: [Shaofeng Liu](#)

1 - WasteLogs: a decision support tool for strategic waste collection

Jérôme De Boeck, Vera Fischer, Meritxell Pacheco Paneque

Waste collection management has seen an increasing interest in the OR community these past years. This is due to the wide range of Capacitated Vehicle Routing Problems (CVRP) studied and the growing trend in studying sustainability-related problems.

For waste collection companies, it can be challenging to identify the type of strategy most suitable for a given situation. On the one hand, the complexity of the state-of-the-art algorithms presented in the literature; on the other hand, the data needed for these algorithms can be challenging to obtain and encode.

In partnership with Alpenluft, a Swiss waste collection consulting company, and the Innosuisse agency supporting R&D projects, we developed the WasteLogs application, a user-friendly strategic waste collection decision tool. The application offers interfaces allowing the encoding of the collection points, the amounts of waste to collect, and the collection strategy in different features that can be combined to generate a routing for collection vehicles. There are currently three state-of-the-art collection strategies implemented in the tool. Each algorithm minimizes the CO2 emissions through heuristic methods; the user can then identify what collection strategy is the most suitable and extract the information needed to import them into GPS systems. WasteLogs also allows importing existing collection tours to evaluate whether they can be improved.

2 - Optimizing Industrial Order Fulfilment: A Decision Support System for Efficient Intra-logistics

Marco Taccini, Giulia Dotti, Manuel Iori, Anand Subramanian

This study addresses the improvement of order fulfilment in industrial settings with centralized order consolidation and distributed warehouses. To ensure homogeneity and customer satisfaction when transporting products to the central facility, logistics operators need to make decisions about warehouse management, transportation modes, stock unit configurations, and product features. Many companies rely on manual information flow to achieve these objectives, resulting in costly and time-consuming operations. Here we propose a Decision Support System (DSS) that integrates information flow digitalization and material flow optimization. Optimization is accomplished through an integer linear programming model that considers all the factors listed above. Digitalization relies on a scalable software infrastructure that periodically gathers commercial information, checks product availability, runs the optimization model, and integrates decisions into the enterprise resource planning system. The DSS was developed in collaboration with an international ceramic tile company. Compared to manually implemented operations, the results reveal a significant reduction in transportation costs, ranging from 24% to 40%, along with estimated time savings of about 120 hours per month. Therefore, the implementation of the DSS offers substantial cost savings by optimizing stock transfers and maximizing valuable working hours.

3 - Managing Transportation and Inventory Simultaneously: A Dual-Objective Approach in Supply Chain Networks with Multiple Distribution Networks

Lokesh Vijayvargy, Saumyaranjan Sahoo

In order to meet customer needs efficiently, logistics plays a crucial role within the broader supply chain by managing the forward and reverse flow, as well as storage, of products, services, and associated data. This study addresses the supply chain network problem, focusing on determining the optimal allocation of orders from multiple plants, warehouses, and distributors. The goal is to minimize total transportation and inventory costs while simultaneously optimizing locations, flows, shipment composition, and shipment cycle times. The formulated problem is treated as a multi-objective programming challenge and is solved using the value function approach to obtain the optimal order allocation of products. A case study on ABC Company's supply chain is conducted to assess the effectiveness and applicability of the developed multi-objective model. The results indicate optimal transportation and inventory costs for ABC Company, along with an optimal distribution network within India. These findings hold significant relevance for the manufacturing sector, especially for those grappling with logistics challenges in their supply chain networks. The developed model equips researchers and managers to navigate various uncertainties and logistics risks associated with supply chain networks.

4 - Exploring the Role of Peer Learning in Supporting Decisions for Food Sharing Organisations

Shaofeng Liu, Xinyi Li, Dulekha Kasturiratne, Huilan Chen

More and more individuals and families have been driven into the danger zone of going hungry recently. To rescue the situation, food sharing organisations (e.g. charities) have worked untiringly. One of the key challenges facing the food sharing organisations is the lack of decision support to help improve their operations efficiency and community of practice. This paper aims to investigate the role of peer learning in the creation of closed-loop social value networks, subsequently to support food sharing organisations and communities.

A Systematic Literature and Practice Review (SLPR) has been undertaken. Based on the SLPR, a comprehensive peer learning framework for food sharing has been developed consisting of four core components: peer learning agents, peer learning modes, peer learning practice, and peer learning outcomes and impacts. The impacts of peer learning on the creation of closed-loop social value networks will be assessed via four stages of the network, including social value propositions, value beneficiaries, value delivery channels, and value capture and feedback. The peer learning framework contributes to new knowledge and practice in a number of aspects: (1) it defines relationships among the four peer learning components; (2) it establishes the main impacts of peer learning on four stages of social value networks; and (3) it provides recommendations to food sharing organisations in making efficient decisions.

Success, Failure And The Factors That Influence Outcomes

Stream: Making an Impact
Invited session

Chair: Sander Van Aken

Chair: Dennis Huisman

Chair: Frédéric Gardi

1 - Success, Failure And The Factors That Influence Outcomes

Making An Impact, Sander Van Aken, Frédéric Gardi, Dennis Huisman, Alberto Delgado

The speakers on this panel all have wide experience of working with stakeholders to deliver projects putting OR into practice. In the first part of the session, each speaker will talk about their experiences and learnings, and how these have shaped their own views on which factors influence whether an application could be (or will be?) a success, a failure or somewhere in-between. We will then invite audience questions, and open up the discussion: do these sound familiar? What are your own experiences? What lessons would you like to share on how to address them?

For final details of speakers, please see the 'Making an Impact' page on the main conference website.

■ TD-47

Tuesday, 14:30-16:00 - Room: 50 (building: 324)

MCDA and urban planning 3

Stream: Multiple Criteria Decision Analysis
Invited session

Chair: Francesca Abastante

1 - A MCDA Model to Support Territorial Planning at the Regional Scale: the Case of Negotiated Planning Tools in the Lombardy Region

Marta Dell'Ovo, Alessandra Oppio, Marco Rossitti, Francesca Torrieri

Nowadays, public territorial planning is called to properly orient public funding toward interventions that ensure long-term sustainability while contributing to collective well-being. For this reason, resorting to integrated planning tools, opened to public-private partnerships, becomes crucial, together with considering their coherence with the reference planning frame. Based on these premises, the research reflects on the evaluation models' role in addressing this coherence issue and supporting territorial planning by implementing negotiated planning tools in the Lombardy Region. Indeed, negotiated planning is a means to address public interest toward territorial development by promoting public-private partnerships. It is ruled by the R.L. 19/2019, which provides an evaluation clause to understand the tools' contribution to achieving regional objectives. Thus, the research aims to define an evaluation model to support the regional administration in ensuring the effective implementation of negotiated planning tools and their compliance with regional strategies. The multi-dimensional nature of the considered issue calls for resorting to Multi-Criteria Analysis. After describing the methodological process to trace the law's provisions into a multi-criteria frame, the evaluation model is tested on some case studies of implemented Agreements in the Lombardy Region. Such a test better highlights the model's opportunities, limits, and improvement room.

2 - A GIS-MCDA Approach for Spatial Assessment of Real Estate Dynamics: a trial in Rotterdam, the Netherlands

Eugenio Muccio, Giuliano Poli, Hilde Remoy, Maria Cerreta

According to the United Nations, while housing is an integral part of 7 SDGs, it makes direct and indirect contributions to all Agenda 2030 goals. In particular, increasing access to affordable housing remains essential for SDG11, addressing the requirements of low-income, vulnerable, and marginalized households while advancing housing affordability for progress towards sustainable communities. The multi-attribute nature of housing is reflected in its market value, determined not only by economic variables (e.g., price, income, GDP) but also by non-economic factors influencing real estate dynamics, specifically in tourism contexts. Establishing a monitoring framework for residential real estate urban dynamics at the neighborhood level is useful for decision-makers in addressing planning uncertainty associated with uneven spatial development, housing affordability, and gentrification. This contribution aims to experiment with spatial composite indicators produced through MCDA aggregating methods to rank urban districts of Rotterdam, the Netherlands, concerning the three above-mentioned phenomena. A set of monetary and non-monetary indicators has been implemented as proxy variables to assess the characteristics of housing stock. Assessing housing values using GIS-MCDA aggregation procedures is still a low-explored field which the authors aim to stress to advance research in the assessment of real estate spatial dynamics at the urban scale.

3 - The grammar of constraints for a things-based justice. Urban text(ure)s and the ulteriority of the local identities

Salvatore Giuffrida, Maria Rosa Trovato, Vittoria Ventura, Cheren Cappello, Ludovica Nasca

Project evaluation derives from operational research method and tools for formalizing decision-making processes. Among these, the Appraisal and valuation discipline privileges the ones aimed at measuring the added value, an aspect of the progress of social communities that implies considerations of distributive justice. Although not universally endorsed, the appeal to the civic engagement of evaluation is increasingly compelling since the succession of economic crises and environmental fluctuations enlarges the frontline of countering the distress of territories and communities. This paper addresses the redevelopment processes of historic urban fabric by proposing a "scenario-generating model" based on a structured and limited set of constraints (rules) able to outline a potentially unlimited number of consistent layouts. On the basis of two different experiences carried out with reference to a

building-urban fabric in Italy, some critical reflections are proposed on: 1. the "grammatical" framework of this system, which bases its internal coherence on the "morphological," "semantic," and "syntactic" levels; 2. the projection of the "ethics of constraint" from the particular dimension of "what is owed" to things and people, to the general dimension of "what is owed" to earth and communities.

Tuesday, 14:30-16:00 - Room: 60 (building: 324)

DEA applications in Policy Making and Planning I

Stream: Data Envelopment Analysis and its Application
Invited session

Chair: Stavros Kourtzidis

1 - The international Efficiency Gap Analysis of Mobile Network Operator markets

Norihiro Hayakawa, Yasufumi Saruwatari

The objective of this study is to clarify the impact of market characteristics of the mobile telecom market in Japan, the Republic of Korea (South Korea), the United Kingdom (UK), and the United States (USA) on the efficiency of management of the Mobile Network Operators (MNOs) in each market. The MNOs are said to be affected by their government policies. In comparison to the efficiencies of MNOs internationally, it is necessary to consider not only the external factors that the MNO can NOT control but also the internal factors that the MNO can control. This study employs "meta-frontier" to separate those factors and clarify the efficiency gap (i.e., the Technology-Gap) between the countries. The Technology-Gap reveals a range of characteristics across international mobile network operator markets: the platform migration strategy (3G to 4G, 4G to 5G), the mobility of customers, the smartphone (device) sales and customer acquiring strategy, the government regulations, and so on. One of the results shows that the global MNO markets can be divided into two categories given the mobility of customers. The markets that have high mobility of customers migrate their generation aggressively and sell smartphones (devices) at lower prices to acquire new customers. The markets that have low mobility of customers tend to cut their service costs and lower their service fees to retain customers.

2 - Analysing the performance of Business Incubators in India using a DEA-Decision Tree approach

M S Karthicanand, Prakash Sai Lokachari

Startups drive economic growth through technological innovations, market expansion, and increased production. This trend is evident globally, with countries like India fostering entrepreneurship through well-funded support structures, notably business incubators. Incubator performance assessment is challenging due to existence of diverse frameworks and objectives. Current literature often overlooks improvement pathways for individual incubators. To address this, we employ Data Envelopment Analysis (DEA) for relative performance evaluation, identifying improvement opportunities without preconceived assumptions. A Classification Decision Tree based on DEA outcomes distinguishes incubator profiles, notably highlighting differences between university-based units and others. Mentoring, infrastructure, and technology support emerge as crucial, especially for Deep Tech startups, which require distinct assistance due to their capital intensity and technological uncertainty. Our study assesses 53 Indian non-profit incubators and reveals variations in profiles that are discussed in the context of supporting Deep Tech startups, making it vital for policymakers and incubator managers navigating the evolving entrepreneurial landscape.

3 - Including a Public Input in the Additive Two-Stage Network DEA Model: The Case of Quantitative Easing in Japan

Stavros Kourtzidis, Giannis Karagiannis, Nickolaos G. Tzeremes

The traditional additive two-stage network DEA model under constant returns to scale has non-increasing decomposition weights (i.e. the weight assigned to the first stage is not less than the weight assigned to the second stage), which also has a direct impact on the stage efficiencies. Previous research has revealed that adding external input/s in the second stage provides the necessary conditions under which there can be a reversal in the decomposition weights for the two stages. In this paper we are investigating the case of an external public input in the second stage, which is shared across DMUs but not allocatable, and its effect on the decomposition weights. The empirical investigation is undertaken using a dataset of Japanese Regional Banks. Bank of Japan has a long tradition with quantitative easing as a monetary policy instrument that could help boost economic activity, avoid deflation, and overcome the problems of the liquidity trap. Given that quantitative easing provides all banks with liquidity, we model it as a constant input in the second stage of the model. This generalised structure of the model with an external single constant input in the second stage tend to produce results which do not suffer from the issues under investigation.

Production planning problems

Stream: Lot Sizing, Lot Scheduling and Production Planning

Invited session

Chair: Christian Almeder

Chair: Daryna Dziuba

1 - Production planning in the automotive industry with Artelys integrated scheduler service

Hugo Chareyre, Maxime Dufour

Efficient and accurate production planning is crucial in the automotive industry. Artelys has developed a scheduler service for Toyota Motor Europe that creates plannings for post-production workshops operations across Europe. The problem consists in scheduling operations on vehicles on different production lines with available resources. This case study details how this industrial problem differs from the classical Resource Constrained Project Scheduling Problem (RCPSP) with its additional operational constraints (multiple shifts, preemptive breaks, sequence constraints, etc.) and its multi-objectives (minimizing late tasks, late vehicles, maximizing efficiency and workers ergonomics, etc.). Artelys has worked closely with Toyota to deploy this scheduler service as micro-service in order to solve this complex problem in a real-time context and as a flexible decision-aid software. The associated constraint programming model is implemented with Fico Mosel modelling language and the model is solved using Artelys Kalis solver. This micro-service has replaced a manual tedious task that was taking place differently in all workshops by delivering faster, higher quality solutions.

2 - Integrated Production and Delivery of Rapidly Decaying Products

Ron Weitzman, Inessa Ainbinder, Gavriel David Pinto, Daniel Lifshitz, Gad Rabinowitz

The goal of this research is to develop models for planning and scheduling production systems of rapidly decaying products. The F-18 radiopharmaceutical cyclotron (RC) production and its delivery is a specific and important example of such a system. F-18 isotopes are

used for medical diagnosis and treatment. The RC production and delivery process consists of five stages: cyclotron, synthesis, vial filling, delivery to the hospital(s), and injection. The produced isotope decays exponentially throughout all these stages. The demand is ordered daily by each hospital, specifying each treatment's dose and time of injection. The research focuses on the basic case of a single cyclotron, single material, and single hospital, which represents many existing radiopharmaceutical production and delivery systems. We develop and analyze a relaxed model for this case, together with a solution scheme for a detailed discrete injection plan. The proposed model is a novel relaxed optimization model with a convex cost function and a set of operations management constraints. The solution determines the number and sizes of the daily cyclotron batches to meet the hospitals' demand while minimizing the costs of production and inventory holding, considering the radioactivity decay. The proposed solution process derives both symmetric solutions (of identical batches) and nonsymmetric solutions. A set of best feasible solutions are presented for the choice of the decision maker.

3 - Optimal Order Quantity for Subcomponent: An Extension of EOQ Model

Yash Aneja

Some components used to assemble a final product are assembled in-house in separate assembly lines. Subcomponents are used to assemble components. Some subcomponents are purchased outside or produced outside the plant and delivered. We want to decide the order quantity of subcomponent which is used in the production of component. As an example, in many auto manufacturing plants, vehicle engine (component) is assembled in-house and used in vehicle (final product) assembly line. Major components (subcomponents) of engine are engine block, crank shaft, piston. . . . Some auto manufacturers assemble engine in-house and make engine block outside the vehicle manufacturing plant and deliver it. We want to find the optimal delivery batch size (order size) of engine block to vehicle manufacturing plant. We develop a mathematical model for the problem and obtain a simple optimal policy.

4 - Solving capacitated lot sizing problems using a combination of fast construction heuristic, metaheuristic and improvement heuristic

Daryna Dziuba, Christian Almeder

The capacitated multi-item lot-sizing problem with setup times is known to be NP-hard. In our recent work, we proposed the 2-step construction heuristic (2-SCH), which delivers competitive solution quality within a short computational time and can be applied to various problem extensions with minimal modifications. It was shown that problem instances with high capacity utilization and high average time between orders are particularly challenging and, in the worst case, only solutions that use overtime capacity could be constructed. Leveraging the structure of the 2-SCH, we explore opportunities to enhance solution quality as well as counteract the possible use of overtime by incorporating the 2-SCH into a metaheuristic and designing an improvement heuristic that relies on information from the 2-SCH solutions.

Omni-Channel Retailing

Stream: Retail Operations

Invited session

Chair: Alexander Hübner

1 - Navigating Omnichannel Grocery Retailing: Bridging Customer Insights for Strategic Decisions

Daniela Fernandes, Pedro Amorim, Jan C. Fransoo, Fábio Moreira

In response to the growth tendency of online sales, grocery retailers have embraced e-commerce, and committed to the required investments. It is a recognized fact that profitability is hard to attain given the costs associated with order fulfillment and last-mile distribution, aggravated by customers' unwillingness to pay additional fees for these services. We consider the case of an omnichannel grocery retailer, that provides home deliveries for a delivery fee, leveraging its Brick-and-Mortar network. Improving the operational efficiency of online order fulfillment is important, but larger opportunities lie in effectively managing demand within and across channels. We use customer-level activity over time to infer the influence of online channel features, such as delivery fees and assortment size, and of the store network on customer behavior. Our findings reveal that customers strategically adjust their shopping habits based on factors like fees, product variety, household needs, and proximity to physical stores. Building on these insights, we model customer behavior regarding store selection, shopping frequency, and expenditure patterns. By considering the cost to serve online orders and the value customers present to the retailer across channels, we prescribe solutions that optimize the retailer's profits. In a series of numerical studies, we draw managerial insights on the path to omnichannel profitability.

2 - Optimal Policies for Handling Returned Products in the Reverse Supply Chain

Nizar Zaarour, Emanuel Melachrinoudis, Sining Chai

Product returns are an essential part of conducting business today, due to the emergence of e-commerce and the proliferation of generous return policies. Such policies, however, can backfire due to their costly operations and unpredictability. To minimize the adverse impact, we develop and compare different collection policies to minimize the combined inventory and transportation costs in a three-echelon network consisting of (a) customers returning products to initial collection points (ICPs), (b) the ICPs, and (c) the centralized return centers (CRCs), that receive the products shipped from the ICPs after they are aggregated into larger shipments to leverage economies of scale. Collection policies are developed for the cases of a single product and a single ICP and CRC; multiple products and a single ICP and CRC; and multiple products with a single ICP and multiple CRCs, by using individual shipment policy where ICPs ship out products to individual CRCs and a combined shipment policy that allows shipping and routing from an ICP to multiple CRCs. Mathematical models are developed to determine the collection period at the ICPs to minimize the combined inventory and transportation costs for these policies. An efficient algorithm is developed, and results are presented with an experimental dataset.

3 - Plan Ahead, Act in Real-Time: Optimization of Driver Capacity Allocation in the Omnichannel Grocery Sector

Javier Rubio-Herrero, Pedro Lopes Gerum, Moonwon Chung, Matteo Giaretti

We collaborate with Glovo, a European technology company in the e-commerce grocery sector, to optimize hourly driver capacity allocations across their stores. We do this by introducing decisions at the strategic, tactical, and operational levels in a multi-tiered framework in which long-term decisions are employed to improve short-term decisions. Our suggested framework demonstrates a considerable improvement over Glovo's current operations when it comes to revenue and delivery costs.

4 - Optimizing Profit and Minimizing Waste: A Bi-Objective Dynamic Programming Model for Inventory Control and Pricing of Perishable Products

Melda Hasiloglu Ciftciler, Onur Kaya

When considering the prevention of food waste, it is worth examining the strategies of perishable food retailers. Inventory management and sale price strategies of perishable food products are essential for retailers to maximize profit and minimize food waste. In our study, we examine the challenge faced by a retailer who simultaneously sells a single type of food product with different ages (old and new), allowing for demand shifts between these products based on sale prices and consumer behaviors. We develop a bi-objective dynamic programming model and find the optimal discounted price, sale price and order

quantity of food products to maximize the retailer's profit and minimize food waste. We formulate four commonly practised static and dynamic pricing policies and quantify the advantage of dynamic pricing and price differentiation between old and new products by considering both profit and waste. Our findings indicate that significant improvements can be obtained by dynamically determining the order quantity and the old product's sale price, considering the current inventory at hand. Moreover, for our bi-objective function, we use the weighted-sum method and we analyze the results of different weight combinations of profit and waste in the objective function. The findings emphasize the significance of waste and sustainability issues, highlight the balance between waste and profit, and offer valuable insights to companies aiming to enhance their system results.

Network Design for Public Transport

Stream: Public Transport Optimization

Invited session

Chair: [Anita Schöbel](#)

1 - Ferry network design and scheduling: an exact optimization model for analysis of pathway alternatives

Michael Sederlin, Tomas Lidén

Owing to the lack of land-based infrastructure connecting islands, ferry-based public transport is often the only feasible means of reliable mass transportation. Ferry transport operating in populated archipelagos consists of a combination of fixed and flexible services, highly variable stopping patterns within lines, a lack of regular operating cycles and a small heterogeneous vehicle fleet. While water bodies separating islands create barriers, the unique geographic layout with many islands in close proximity also offers large routing freedom. Taking advantage of novel pathways may require cost-inducing efforts such as depth surveys, dredging or marking shallows. We present a joint method for ferry routing and scheduling based on a multi-trip vehicle routing problem approach. The proposed model incorporates many of the observed characteristics of real systems. Traffic requirements are included as minimum stop visits over the scheduling period and as window-constraints. Evaluation of novel pathways is supported in the form of arc-bundles with fixed opening costs. The computation time is shown to be sensitive to the number of window constraints. Full system solutions with an optimality gap between 10 and 15 % are obtained within a time-scale reasonable for strategic planning. Our results show that pathway evaluation and operational assessment need to consider the traffic requirements and fleet characteristics at hand.

2 - Scenario-driven Algorithm Selection for Transportation Planning Problem

Zhang Jiarui, Xiaojie Luan, Li Haiying, Yifan Zhang

Countless algorithms have been developed to tackle transportation planning problems. However, there is no one-size-fits-all algorithm that can ensure absolute superiority in all scenarios. To improve solving resilience across various instances and demands, we take Service Network Design Problem (SND) as a starting point. A Convolutional Neural Network-based method is proposed to distill and represent the feature of the instance and demand. Meanwhile, historical solving data are used to train a machine learning module for selecting the best candidate algorithm. This module is embedded into an algorithm framework, employing several algorithms to solve diverse instances under various solving demands. Numerical experiments reveal that the proposed method has superior solving resilience compared to individual and random algorithms utilization.

3 - Optimizing stopping patterns in public transport

Anita Schöbel, Ricardo Reicherz, Sven Jäger

In order to increase the travel speed of trains or buses in public transport, it may be beneficial to skip some stops on their routes. In such skip-stop services, a line is divided into two sublines (let's say a green and a red one) which are operated alternately. The stations are also divided into two sets with usually non-empty intersection, a set of green and a set of red stations. The green line only stops at green stations and the red line only stops at red station. With such a pattern, it is possible to increase the travel speed of the trains. However, there now may exist pairs of stations which have no direct connection any more forcing passengers to transfer between the red and the green line. It may even happen that passengers have to take a detour to travel from an origin to a destination.

We consider the problem of designing skip-stop patterns from a passenger-oriented point of view. Given a number p of stops to be left out (together in both lines) and a set of origin-destination pairs representing the passengers' demand, we aim at finding stopping patterns that minimize the number of transfers, the number of passengers who need a detour, or the traveling time of the trains. For all three objectives we provide IP formulations and characterize optimal solutions. We then combine these objectives and show which of them are in conflict and which of these goals can be reached simultaneously. The results are illustrated at examples.

4 - Comparative analysis of a Stackelberg model and a multi-objective model for the design of urban transportation networks

Mauricio Cepeda Valero, Jose Fidel Torres Delgado, Andres Gonzalez, Luis Felipe Jimenez Sanchez

Urban transportation network design is a crucial area of research. However, there is a lack of comparative studies between different optimization techniques, primarily due to the unique nature of each method, adapted to specific problem structures. This study aims to address this gap by evaluating two models—Stackelberg and multi-objective—for urban transportation network design. In the Stackelberg model, users lead transport system usage decisions, while the transportation provider follows. Conversely, the multi-objective model considers both user and provider objectives simultaneously. These models are represented as multi-layer network flow problems, and they aim to optimize network expansion and flow distribution, balancing the provider's cost minimization objective with user objectives of minimizing travel time and network accessibility time. The evaluation of these models involves measures such as betweenness, edge flow, accessibility, and demand compliance. The models are applied to four types of topological networks representing city transportation systems: mesh, hub and spoke, linear, and tree structures. The results indicate that the mesh network modeled by the Stackelberg model achieves the highest accessibility and cost efficiency. Thus, the study contributes to the understanding of urban transportation network design by providing insights into the performance of different optimization models and their applicability in various network structures.

Integer Programming and Combinatorial Optimization: Complexity Questions and Algorithms

Stream: Combinatorial Optimization

Invited session

Chair: Sergei Chubanov

1 - Some results on an extension of the vertex cover problem

Juan F. Correcher, Mercedes Landete, Juanjo Peiró, Hande Yaman

The relationship between locations and their connections can be modeled by using some extensions of the vertex cover problem. In this talk, we revisit some of these extensions and provide new ideas that can be used in solution methods. The applicability of our proposals is tested in a branch-and-cut algorithm on several computational experiments, the results of which will also be discussed.

2 - Assessing Network Cohesion Using the Collapsed k-Core

Domenico Serra, Martina Cerulli, Carmine Sorgente, Claudia Archetti, Ivana Ljubic

In social network analysis, the size of the k -core, representing the largest subgraph with minimum degree k , is often used to measure community cohesion. The Collapsed k -Core Problem aims to identify a subset of crucial users, whose removal results in the smallest k -core. We formulate this problem using mathematical programming for the first time. One approach employs an Integer Linear formulation, modeling deletion rounds. Another approach presents two bilevel programs, differing in their formulation of the k -core identification. We reformulate the first bilevel model as a single-level sparse model using a decomposition method. For the second model, we provide a linear formulation for k -core identification and dualize it, resulting in a compact single-level Mixed-Integer Nonlinear problem. We also outline preprocessing steps and valid inequalities for all formulations. Performance comparison is conducted against a state-of-the-art solver on benchmark instances.

3 - On finding dissimilar paths with different dissimilarity weights: a comparative approach

Marta Pascoal, Maria Teresa Godinho

The resilience of the solution for routing problems may be affected if the solutions share many network resources. The problem of finding sets of K paths between given origin and destination nodes in a network which minimize a total cost function and maximize the paths dissimilarity intends to promote the search for low cost solutions that simultaneously have little in common to one another. That problem was addressed recently based on bi-objective single-commodity and discretized flow formulations which model the similarity based on two assumptions: the minimization of the number of arc reuses and the minimization of the number of pairwise arc overlaps. In the present work we review the bi-objective linear integer formulations and compare this bi-objective approach with single-objective formulations where the similarity measure is weighted differently depending on the sensitivity of the area of the network where arcs may be shared.

4 - On the complexity of optimizing black-box functions in oracle models

Sergei Chubanov

We discuss algorithmic complexity of general discrete nonlinear optimization models with augmentation, verification, and evaluation oracles. We show that in many situations where at least a verification oracle is available, which verifies whether a given solution is optimal, an optimal solution for the respective discrete optimization problem can be found in strongly polynomial oracle time. Also, we discuss algorithms based on machine-learning methods with performance guarantees for practical black-box optimization scenarios of large-scale scheduling problems and optimization problems with partial differential equations where only evaluation oracles are available.

Resilient Networks

Stream: Sustainable and Resilient Systems

Invited session

Chair: Miriam Sarkis

1 - Securing Network Resilience: Leveraging Node Centrality for Cyberattack Mitigation and Robustness Enhancement

Essia Hamouda

In response to the dynamic and ever-evolving landscape of network attacks and cybersecurity, this study aims to enhance network security by identifying critical nodes and optimizing resource allocation within budget constraints. We introduce a novel approach leveraging node centrality scores from four widely-recognized centrality measures. Our unique contribution lies in converting these centrality metrics into actionable insights for identifying network attack probabilities, providing an unconventional yet effective method to bolster network robustness. Additionally, we propose a closed-form expression correlating network robustness with node-centric features, including importance scores and attack probabilities. At the core of our approach lies the development of a nonlinear optimization model that integrates predictive insights into node attack likelihood. Through this framework, we successfully determine an optimal resource allocation strategy, minimizing cyber-attack risks on critical nodes while maximizing network robustness. Numerical results validate our approach, offering further insights into network dynamics and improved resilience against emerging cybersecurity threats.

2 - Capacity planning to manage the operation of redundancy installations

Flávia Barbosa, Mariana Casalta, Ana Camanho, Jaime Gabriel Silva

One of the biggest challenges in efficiently managing any organisation is drawing up a conscious strategic capacity plan. Therefore, it is essential to draft a mid-term tactical capacity plan with singular and measurable objectives. This work focuses on the business activity of urban water utilities, which is often faced with economic, operational, and institutional constraints, and it is fundamental to optimise their business activity. In this context, the water-energy nexus is important to these utilities, as it describes the relationship between the water used for energy production, including electricity and fuel sources, and the energy consumed to capture, treat, and supply water. The energy represents one of the highest financial costs for these organisations. We propose a methodology to minimise energy expenditure in urban water supply service. It includes a mid-term tactical capacity planning for a Portuguese water utility over three years. A water supply network usually has five groups of infrastructure: catchments, pipelines, reservoirs, pumping stations, and water treatment plants, which can have redundancy installations. The energy consumption can be minimised by managing the operation of redundancy installations. In this way, it is possible to make the most use of the organisation's assets, considering its energy costs and the forecast of the average demand for water by the region's population.

3 - Decision-support tool for resilient biopharmaceutical supply chains

Miriam Sarkis, Nilay Shah, Maria Papathanasiou

Supply chain resilience is a growing priority in the biopharmaceutical sector. In recent years, the industry has seen the market boom of next generation therapies against life-threatening diseases and the urgent demand for vaccines during the pandemic. Manufacturers catering for these markets reported shortages and delays due to unforeseen demand trends combined with uncertainty in manufacturing capabilities for platforms still under development. We present a decision-support tool that can help assess supply chain resilience a priori for networks that require rapid scale-up to commercialisation and operate under supply-demand uncertainty. Firstly, the propagation of underlying manufacturing uncertainty to scale dependent throughput-related and cost-related KPIs of manufacturing at the investment level is assessed via uncertainty analysis and global sensitivity analysis. Secondly, a stochastic mixed-integer linear problem is formulated for the optimisation of investment planning under process and demand uncertainty. Finally, we introduce a scenario-based supply-demand chance constraint, which quantifies manufacturing supply robustness in meeting target demands. Solution feasibility is tested via Monte Carlo based simulation. Candidate investment plans for single-product and multi-product systems are assessed and cost-resilience Pareto frontiers are

constructed via the ϵ -constraint method to support decision-makers allocate resources to reliable manufacturing systems.

1 - Rerouting Heuristic for the Congestion-Aware Dial-a-Ride-Problem Considering Intersection Capacities

Paul Rieger, Arturo Crespo Materna, Andreas Oetting

Given recent social and technological developments, the consideration of the Dial-a-Ride-Problem (DARP) in large-scale ridepooling has gained more importance as a sustainable and increasingly viable alternative to personal motorized vehicles. In reality, routing decisions for DARPs in large-scale ridepooling effectively influence traffic conditions and the resulting travel times in the network. Since routing decisions are mostly based on travel times, a mutual dependency between routing decisions and travel times emerges. Recent research on DARPs in large-scale ridepooling provides solutions for congestion-aware routing and vehicle assignment while the modelling of infrastructure capacity is based on traffic dynamics within links. The main feature of the presented approach is the modelling of infrastructure capacity and its impact on driving and waiting times, extending beyond links to include intersections with adaptive signal control. The novelty of the suggested approach is twofold. Firstly, a new analytical approach for modelling infrastructure and its capacity is provided while considering mutual dependencies between flow capacities within intersections in case of adaptive signal control. Secondly, a heuristic is derived to optimize a given initial solution of a DARP with the aim to optimize capacity consumption of infrastructure while maintaining constraints of a typical DARP. The results are shortly demonstrated within a small case study.

2 - Insertions with lookahead for dynamic ridepooling services

Arne Schulz, Christian Pfeiffer

Due to the required reduction of emissions, modern mobility concepts are rapidly evolving. Ridepooling is one of these concepts. Beside the reduction of emissions due to electric vehicles, ridepooling services promise to reduce traffic due to pooling and to increase mobility access especially in suburban areas. In practice, ridepooling services receive customer orders dynamically and thus have to integrate them in the vehicles' tours. In this talk, we discuss an efficient procedure to insert new customer requests into given tours while incorporating possible future customers with the objective to serve as many customer requests as possible over the time horizon.

3 - Online routing for Demand Adaptive Systems

Maximilian Schiffer, Benedikt Lienkamp

As urban populations continue to grow, traditional static and fixed-route transportation systems face unprecedented challenges to meet societies' dynamic and diverse mobility needs. Demand adaptive systems (DAS), which combine traditional fixed bus lines and demand-responsive systems, have emerged as a promising paradigm in public transportation to address these challenges. DAS provides traditional transit-line service for a set of compulsory stops. These compulsory stops are bound to a schedule with fixed time windows during which the vehicle serving the line has to leave each compulsory stop. Passengers may issue requests at optional stops, inducing detours in the vehicle routes. Focusing on the operational phase, where we adjust vehicle routes and schedules in response to user requests, we formulate and solve a variant of the dynamic single-vehicle routing problem with time windows and profit. We propose an algorithmic framework based on a set of dynamic user requests containing both optional and

compulsory stops. We present a machine learning enriched integer programming framework that enables a DAS operator to select a subset of requests to serve while maximizing its expected profit. Here, we determine a route serving all selected requests, respecting compulsory stops' time windows. With this algorithmic framework, we compare traditional fixed-route transportation systems with DAS in Munich and present managerial insights from the operator's and user's perspectives.

4 - A Framework for building Last Mile Connectivity to Urban Public Transit Systems in India

Murari Srinivasa, Rajluxmi V. Murthy, Reshma Chandrasekharan

Multimodal public transit is an integral part of urban passenger transport in rapidly urbanizing modern economies. Public transit systems need strong, tightly-coupled last mile connectivity for continued patronage. In this paper, we deploy a spatial analytics and optimization-based approach to create a replicable framework which identifies and addresses gaps in last-mile connectivity to a planned urban public transit system such as the metro rail. We draw on classic transportation literature on the feeder network design problem and more recent research on last mile transportation systems, while adding to optimization literature on NP-Hard variants of the generic spanning tree problem for an undirected graph to provide an optimal set of last-mile stops and route structures. We demonstrate our framework through a systematic deconstruction of publicly available spatial/demographic data on an urban agglomeration in India (Bengaluru, Karnataka) and its metro rail infrastructure under development. Our findings show that the proposed long-term metro rail covers about 49% of the current population of 5.8 MM who reside within a walking distance from the proximal station. We identify stops and potential route structures for a fixed last-mile feeder network system which can potentially add a further 33% to the coverage. We also identify zones and segments of the city and its population for consistent planning of the built environment to facilitate better last mile connectivity.

1 - Consistent Collaborative Vehicle Utilization

Sahand Asgharieh Ahari

Carriers are driven by the dual objectives of minimizing delivery costs and maximizing customer satisfaction. Collaboration can reduce cost, while service consistency enhances customer satisfaction. To address these objectives concurrently, we introduce a multi-period collaborative model which we term "consistent collaborative vehicle utilization" framework. In this framework, carriers can borrow trucks from each other, facilitating deliveries to their respective customers, all while adhering to defined consistency measures. In our framework, the borrowed truck first departs from the lender's depot to the borrowing carrier's and then visits delivery locations based on optimal routing decisions. The consistency measures implemented ensure that customers are served exclusively by their designated carrier and at approximately the same time during periods when demand exists. Carriers select delivery times from a set of options specified by customers which is known as time window assignment problem. We formulate the consistent collaborative vehicle utilization problem as an integer programming problem and develop a branch-and-price algorithm to solve it. Additionally, to address larger instances, we propose two heuristics employing column generation technique. Our experiments shows that the consistent collaborative vehicle utilization framework can lead to a remarkable reduction of up to 43% in the number of vehicles, accompanied by a substantial profit increase of up to 15%.

2 - Continuous approximation model for estimating average tour length in prize collecting traveling salesman problem

Daisuke Hasegawa, Yuichiro Miyamoto, Toshio Nemoto

The prize collecting traveling salesman problem (PCTSP) is to find routes and subset of nodes that minimize a tour distance with the constraint to be less than given rewards by visiting nodes. This study estimates the PCTSP travel distance using a continuous approximation model. Continuous approximation model does not search for routes, but it estimates the travel distance using the area of the region and the number of nodes. In our proposed model, the size of the delivery zone and the number of nodes is given, and the spatial distribution of the penalty is represented as a demand function. It replicates the concentration of population and economic value in the center of cities. The function makes it possible to determine the range of the penalty and the average trip distance within the zone. In addition, we propose a method for estimating the PCTSP travel distance in multiple delivery zones. It takes into account the distance between regions and the relative balance of demand and distribution. The method is expected to be applied to the evaluation of priority areas where delivery services such as home delivery, food delivery, and carpooling.

3 - The Full Truckload Pickup and Delivery Problem with Truck Platooning

Yilin Wang, Junlong Zhang

Truck platooning is a promising technology for reducing energy consumption, increasing vehicle safety, and improving traffic efficiency. In this research, we examine the cost-effectiveness of truck platooning from the perspective of a freight company performing full truckload pickup and delivery tasks over a transportation network. We propose two model formulations for this problem: a direct delivery model and an indirect delivery model, where the indirect delivery model allows trucks to visit intermediate locations during deliveries to facilitate the formation of platoons. We devise an improved dynamic discretization discovery (DDD) algorithm to solve the two models exactly. Through extensive computational experiments, we find that (1) the improved DDD algorithm can increase solution accuracy with much less computational effort compared with the original DDD algorithm; (2) the cost-saving effect of truck platooning is favorable, with an average of 80.55% trucks being followers in platoons; and (3) for freight companies operating on small transportation networks, using the direct delivery model may be more appropriate.

4 - The multi-product pickup and delivery problem with time windows and alternative destinations.

Mikele Gajda

We introduce and investigate the multi-product pickup and delivery problem with time windows and alternative destinations. In this problem, we consider a fleet of vehicles with a predetermined capacity for serving multiple customer orders simultaneously. Each order consists of a collection of products, possibly with different pickup locations, and a set of potential delivery points with specific time windows for customer service. To comprehensively investigate the problem, we construct an extensive set of instances that build upon the well-known CVRPLIB dataset. We provide a formal problem description formulated as a MILP and obtain optimal solutions using a branch-and-bound approach. Finally, considering the problem's inherent complexity, we propose a hybrid adaptive large neighborhood search. Our algorithm demonstrates effectiveness in obtaining satisfactory solutions for medium and large-scale instances, which typically pose challenges for exact methods.

1 - Linking freight transport and energy system models for coherent strategic investments decisions

Celine Pagnier, Steffen Bakker, Pernille Seljom

The decarbonization of the transport sector is deeply intertwined with the evolution of the energy system. While modifications of the transport energy demand are often put forward in transport models, there is seldom any discussion on the long-term effects of the newly needed energy-related infrastructures. To investigate this issue, we perform a quantitative analysis of the reciprocal dependencies between modal and fuel shift in freight transportation and energy systems, including energy infrastructure investments.

A soft-link is established between IFE-TIMES-Norway, an energy system model based on linear programming, and STraM, a freight transport model whose focus is on long-term infrastructure investments decisions in a multi-stage stochastic mixed-integer linear program framework. STraM generates an energy demand for the transport sector based on endogenously computed modal and fuel splits, which is fed into TIMES. Reciprocally, TIMES enhances STraM with its economic representation of technologies and evolution of fuel mix. We provide adaptable methods to reconcile disparities in resolution and aggregation between those models.

Then, comparative analyses allow to demonstrate the framework's improvement over the use of a single model and offer insights into the intricate dynamics of the transport-energy nexus. Finally, the gained knowledge is applied to a Norwegian case study to analyze coherent strategic investments decisions for the next few decades.

2 - High-resolution Platoon Prediction for Coordinated Traffic Control along Urban Arterials

Zakir Farahmand, Oskar Eikenbroek, Eric van Berkum

Smooth progression of platoons of vehicles along urban arterials can significantly contribute to environmental objectives, especially when heavy-duty vehicles are involved. Generally, signal controls such as fixed-time, vehicle-actuated and adaptive aim to minimise delays, which may conflict with reducing the number of stops to improve air quality and GHG emissions. Overcoming this challenge requires dynamically synchronising the signal timings of a series of intersections with approaching vehicles to simultaneously reduce delays and the number of stops. A fundamental prerequisite of such controls is real-time prediction of platoon dynamics including forming, dispersion, stopping and arrival after departing from upstream. Existing coordination methods usually focus on flow estimation at aggregate levels, losing critical information for multi-criteria signal operations. Our study introduces a novel method for predicting platoons' dynamics with high resolution under mixed-traffic environments. Utilizing various data sources, including loop detectors, vehicle-to-infrastructure (V2I) communication and floating car data, we employ attention-based graph neural networks to predict platoon arrival and stop times while considering current and anticipated signal phases. Experiments conducted on real-world datasets from an arterial in Enschede, the Netherlands, reveal the suitability of our approach for coordinated signal controls to reduce the number of stops and enable green waves.

3 - A space-time-energy flow-based integer programming model to design and operate a regional SAEV system and corresponding charging network

Gonçalo Santos, Sebastian Birolini, Gonçalo Correia

Shared automated vehicles are expected to be part of the supply of transportation systems in the future. Parallel to this evolution, there is the rapid penetration of battery electric vehicles (BEVs). The limitations in battery capacity and charging speed of BEVs can influence the planning and operation of shared automated electric vehicle (SAEV) systems. The design of such systems needs to include these limitations so that their viability is properly estimated. In this paper, we develop a space-time-energy flow-based integer programming (IP) model in support of the strategic design of a regional SAEV system. The proposed approach optimizes the fleet (size and composition) and charging facilities (number and location), while explicitly accounting for vehicle operations in aggregated terms (including movements with users, relocations, and charging times). The model is used to assess the impact of vehicle range and different types of chargers in the optimal design of an interurban SAEV transport system in the center of Portugal. Link to paper: <https://doi.org/10.1016/j.trc.2022.103997>

4 - Aligning the Public Charging Infrastructure to the EV Driver: Lessons from Brussels and San Francisco

Simon Weekx, Ona Van den bergh, Lieselot Vanhaverbeke, Gil Tal

The transition towards Electric Vehicles (EVs) is an important step to reduce greenhouse gas emissions and local air pollution. An important obstacle for the large-scale adoption of EVs is the availability of sufficient public charging infrastructure. To determine how much infrastructure is needed, scholars often rely on EV adoption data or transactional charging data at existing stations. However, a major drawback of these studies is that they extrapolate the charging behavior of the early EV adopters, which may not be representative for the entire population.

In this study, we present a two-step approach to analyze the impact of different behavioral charging scenarios on the required number of chargers. Based on two large-scale datasets of charging transactions in Brussels and San Francisco, we first employ K-means clustering to find segments of EV drivers that exhibit similar charging behavior in terms of where, when, and how much energy they charge. Second, we develop a Discrete Event Simulation model to determine how much additional charging infrastructure is needed to accommodate an increase in charging activity in each of the behavioral segments. Our results indicate that, depending on the behavioral type, up to 8 times more infrastructure is needed to accommodate the same increase in demand. This highlights the potential for behavior-steering policies such as dynamic- and penalty pricing to make more efficient use of the available charging infrastructure.

Large-scale network optimization and inventory management

Stream: Optimization at Amazon

Invited session

Chair: George Iosifidis

Chair: Daniel Guimaranas

1 - Large Scale Topology and Connectivity Design with In-Network Processing

. Faheem, Onur Can Saka, George Iosifidis, Amit Kumar

Topology and connectivity design with in-network processing (sortation, cross docking) is a critical component for Middle Mile transportation network design to achieve operational efficiency, cost-effectiveness, and delivery speed. In this paper, we consider a middle mile transportation network that consists of warehouses, sortation centers and delivery stations. Given a warehouse to delivery station volume forecast, our goal is to design cost and speed optimal transportation network. We formulate the topology and connectivity design problem as a Mixed Integer Linear Programming (MILP) problem, which

is NP-hard. We describe the key characteristics of the problem and analyze the arising modeling and optimization challenges. To solve large scale real-world problems (>100 million variables), we present our optimization-based matheuristic pipeline, which comprises preprocessing and path pruning strategies, local neighborhood search, and incremental model solving. We show the efficacy of our model using a range of operational datasets. We conclude with potential research threads that can further improve the solution quality and runtime.

2 - A scalable solution to joint routing and sorting problems

Charupriya Sharma, George Iosifidis, Daniel Guimarans, Amit Kumar, Georgios Paschos

We study the joint routing and sorting problem in Amazon's middle mile network, which optimizes the routing of packages from fulfillment centers to delivery stations by using intermediate hubs to sort and consolidate flow. Packages are sorted into pallets, and packages in the same pallet are routed over the same path unless the pallet is dismantled in some intermediate hub. While the problem resembles a multi-commodity flow optimization problem, the operational constraints related to connectivity and sorting capacities and decisions create additional complications for routing that are not present in the literature.

We present a scalable, edge based model to solve this problem using a combination of search space reduction via edge pruning, a warm-start heuristic based on combinatorial optimization and a tight MIP formulation which uses a destination based aggregation of commodities. We observe significant improvements over path-based formulations in both run time and overall costs.

3 - Inventory Decentralization Tailored to Product Demand in Delivery Speed-Sensitive Logistics Networks

Katja Meuche, Yuan Li, Amitabh Sinha, Benoit Montreuil

Large retailers such as Amazon offer a vast array of products, encompassing millions of unique items. The multitude of products creates a complex demand landscape where high-demand products are classified as "head," moderate-demand as "body," and low-demand as "tail." To control complexity and achieve efficiency in the fulfillment network, Amazon regionalized its operations in the US. This process involved defining regions, assigning fulfillment centers accordingly, and aiming to meet customer demands using the inventory of the fulfillment centers within each region. This prompts the crucial question: What level of inventory decentralization is economically beneficial for each product category when considering the customer's sensitivity to delivery speed? In this talk, we report on a large-scale case study focusing on the 48 contiguous US states. We present our methodology, which leverages adapting the Newsvendor model to incorporate transportation costs and order-to-delivery-time sensitivity. We finally present key insights from the study, notably that (1) profit maximization calls for decentralization of inventory for head and body products and more centralization of tail product inventory, and (2) a nuanced approach to inventory decentralization, and hence, region definition based on the product category, is essential.

For the cost-efficient supply of stores, it is common in retail practice to rely on third-party logistics providers (3PL) instead of their own fleet. A 3PL carries out the retailers' delivery tours and commonly bills according to a zone-based tariff. This tariff assigns each store to one zone that reflects the travel distances for the delivery. Stores further from the depot are assigned to higher zones. The cost of a tour depends on the furthest zone visited and the volume, subject to discounts. Additionally, 3PLs limit the detour of a tour to ensure economic feasibility. The detour limitation prevents excessive driving within the zones visited. While using 3PLs and their zone tariffs reduces the complexity for retailers, the question arises of how retailers can plan cost-minimal tours that are economical for 3PLs. We address this issue and formalize the problem as a Capacitated Vehicle Routing Problem with a Zone Tariff. The nonlinear tariff and the non-monotonically increasing detour drive the complexity. We provide the first mixed-integer formulation (MIP) for the problem, which we strengthen with valid inequalities. We develop a logic-based Benders decomposition algorithm (LBBDD) to solve larger instances and improve it with problem-specific acceleration techniques. In our numerical experiments, we solve a real-world case and adapted instances from the literature. The LBBDD approach reduces the runtime compared to the MIP by up to one order of magnitude.

2 - The Cumulative School Bus Routing Problem: Polynomial-Size Formulations

Farnaz Farzadnia, Jens Lysgaard, Tolga Bektas

This article challenges the conventional notion that minimizing shortest paths guarantees the fastest passengers arrivals at destinations. Instead we present a fresh perspective in the school bus routing problem. This article introduces the cumulative school bus routing problem, which the objective of the problem is to select a drop-off point for each student among potential locations within a certain walking distance and to generate routes such that the sum of arrival times of all students from their school to their homes is minimized. The article describes six polynomial-size mixed integer linear programming formulations based on original and auxiliary graphs, and the formulations are numerically compared on real instances. The article reports the results of computational experiments performed to evaluate the performance of the proposed models.

3 - An Exact Approach For The Time Window Assignment Traveling Salesperson Problem With Stochastic Travel Times

Francesco Cavaliere, Matteo Fischetti, Roberto Roberti, Domenico Salvagnin

This study centers on the Time Window Assignment Traveling Salesperson Problem with Stochastic Travel Times, marking a shift from a cost-focused strategy to a more balanced approach that considers both cost and service quality aspects in delivery operations. This research aims to address the challenge of integrating real-world uncertainties, particularly stochastic travel times, into the optimization process. When treated as a two-stage stochastic problem, the first stage involves making decisions about routing and time window assignment using binary and possibly continuous variables. This is followed by handling continuous variables associated with time window violations in the subsequent stage.

This work contributes to the ongoing exploration of vehicle routing, emphasizing the critical role of time window assignment in the optimization framework. Existing literature provides limited methodologies for this specific problem (Celik et al. 2023). In response, we introduce a novel formulation inspired by the Fox et al. three-index formulation for the Time-dependent Traveling Salesperson Problem (Fox et al. 1980). Employing Benders Decomposition as a versatile solution framework, our approach exhibits substantial advancements over prior state-of-the-art solutions for this problem.

4 - An Enhanced Dynamic Discretization Discovery Algorithm for the Continuous-Time Service Network Design Problem

1 - Logic-Based Benders Decomposition for a Capacitated Vehicle Routing Problem With a Zone Tariff

Niklas Tuma, Alexander Hübner, Manuel Ostermeier

Service Network Design Problems (SNDPs) are prevalent in the freight industry, holding significant practical value in their solutions. While the classic SNDP is often defined on a planning horizon discretized into a finite number of integral time units, the Continuous-Time Service Network Design Problem (CTSNDP) operates on a continuous-time planning horizon to avoid errors from discretization. Existing algorithms for CTSNDP and its variants primarily adopt a Dynamic Discretization Discovery (DDD) solution framework. This framework iteratively refines a finite set of integral time units, constructs a partially time-expanded network based on the discretization, and leverages the network to derive relaxations and feasible solutions for the problem. However, DDD algorithms face limitations in computational performance, especially when handling instances characterized by a high-cost ratio of vehicle-based costs over flow-based costs and high time flexibility. Consequently, a substantial portion of these instances remains unsolved. In this study, we enhance the DDD method for CTSNDP by introducing a new initial discretization, a novel exact method for deriving upper-bound solutions, and an improved refinement strategy. The computational study demonstrates that, with these innovative components, the enhanced DDD algorithm exhibits exceptional performance.

Pricing and applications

Stream: Pricing and Revenue Management
Invited session

Chair: [Vienna Klein](#)

1 - A Dynamic Compensation Strategy to Leverage Occasional Drivers in Last-Mile Delivery

Rouven Schur, Kai Winheller

Amid the rapid growth of online retail, last-mile delivery faces significant challenges, including the cost-effective delivery of goods to all customers. Accordingly, the development and improvement of innovative approaches thrive in current research. Our work contributes to this stream by applying dynamic pricing techniques to effectively model the possible involvement of the crowd in fulfilling delivery tasks. The use of occasional drivers (ODs) as a viable, cost-effective alternative to traditional dedicated drivers (DDs) prompts the necessity to focus on the inherent challenge posed by the uncertainty of ODs' arrival times and willingness to perform deliveries. We introduce a dynamic programming framework that offers individualized pairs of delivery task and compensation to ODs as they arrive. This model, akin to a reversed form of dynamic pricing, accounts for ODs' decision-making by treating their acceptance thresholds as a random variable. Thereby, our model addresses the dynamic and stochastic nature of OD availability and decision-making. We analytically solve the stage-wise optimization problem, outline inherent challenges such as the curses of dimensionality, and present structural properties. Designed to cope with these challenges, our approximation methods aim to accurately determine avoided costs, which are a key factor in calculating optimal compensation.

2 - Pricing Decisions with Loading Guarantee Service in the Container Shipping Industry under Capacity and Demand Uncertainties

Tigar Putri Adhiana, Dongping Song, Shu Guo

In container shipping industry, container rollover (i.e. the container cannot be loaded onto the vessel that has been booked) is a common phenomenon, which is largely caused by uncertainties in demand, supply and operations. For example, in 2021, the global container rollover ratio was in the range of 30% 50% due to the COVID-19 disruption and the capacity crunch. The rollover phenomenon has a significant negative impact on shippers because their shipments will be delayed,

and their operations will be disrupted. Recently, some shipping lines such as Maersk and Hapag-Lloyd have introduced an additional service called loading guarantee to shipping to differentiate them from other shipping lines and gain competitive advantage. In this study, we investigate the load guarantee service pricing problem in the container shipping industry. Specifically, we formulate the optimization problem of the pricing decisions of both loading guarantee service and freight rate for an ocean carrier. To examine the effects of capacity and demand uncertainties on the pricing decisions, we model the uncertainties in three scenarios: (i) pricing decisions considering capacity uncertainty, (ii) pricing decisions with demand uncertainty, and (iii) pricing decisions considering both capacity and demand uncertainties. Analytical analysis and numerical experiments are conducted to demonstrate the effectiveness of the models and results.

3 - From approximation errors to optimality gap - exploiting structural knowledge of opportunity cost in integrated demand management and vehicle routing problems

Vienna Klein, David Fleckenstein, Robert Klein, Claudius Steinhardt

The widespread adoption of digital distribution channels both enables and forces more and more logistical service providers to manage booking processes actively to maintain competitiveness. As a result, their operational planning is no longer limited to solving vehicle routing problems. Instead, demand management and subsequent vehicle routing problems are integrated to steer the booking process with the aim of optimizing the downstream fulfillment operations. The resulting integrated demand management and vehicle routing problems (i-DMVRPs) can be modeled as Markov decision process and, theoretically, solved via the well-known Bellman equation. Unfortunately, the Bellman equation is intractable for industry-sized instances. Thus, in the literature, i-DMVRPs are often addressed via opportunity cost approximation approaches. However, the overall performance of the respective approaches largely varies between different instance structures. Furthermore, to the best of our knowledge, there is neither a structured procedure to analyze the corresponding root causes nor general guidelines on when to apply which class of approximation approach. In this work, we address this gap by proposing a structured method to analyze, explain and compare the performance impact of different opportunity cost approximation-based solution approaches for i-DMVRPs. Further, we identify common patterns in approximation errors and derive general guidelines for an informed algorithm development process.

Resource constrained scheduling

Stream: Project Management and Scheduling
Invited session

Chair: [Joanna Józefowska](#)

1 - An FPTAS for scheduling with resource constraints

Bo Chen, Vitaly Strusevich

We study a basic scheduling problem with resource constraints: A number of jobs need to be scheduled on two parallel identical machines to minimize the makespan, subject to the constraint that jobs may require a unit of one of the given renewable resources during their execution. For this NP-hard problem, we develop a fully polynomial-time approximation scheme (FPTAS). Our FPTAS makes novel use of existing algorithms for the subset-sum problem and the open shop scheduling problem.

2 - A bi-objective production scheduling problem with entrant flows and labour resource constraints

Johanna Mlekusch, Richard Hartl

This work introduces a production problem inspired by a real-world company, where the manufacturing process reflects a re-entrant flexible flow shop scheduling problem. Notably, in addition to the re-entrant feature, the challenge involves allocating additional resources, namely, workers, to specific production steps. This scenario can be characterized as a scheduling problem with dual-resource constraints. A key aspect of the problem is the consideration of a cross-trained workforce, allowing workers to transition between stages during production. Furthermore, we consider a heterogeneous workforce, where workers can be differentiated through their skill level, which is defined by the number of stages they can operate on. The objectives of the problem are to minimize the maximum completion time and production costs influenced by employee salaries, reflecting their skill level. The payment structure assumes that each worker is paid for the period starting from their earliest operation starting time until the latest completion time including idle intervals in between. The bi-objective problem is solved using constrained programming and lexicographic optimization. To provide a comprehensive overview of solutions, prioritizing the makespan objective, the epsilon-constraint technique is employed to identify the set of non-dominated solutions. Preliminary findings suggest a substantial potential for cost reduction while maintaining the same throughput.

3 - Bi-objective based scalable balancing of a reconfigurable assembly line

Siwar Arbi, Audrey Cerqueus, Evgeny Gurevsky, Alexandre Dolgui

Balancing an assembly line involves assigning a required set of tasks to a given set of workstations, subject to task precedence constraints and achieving some production goals. The two studied goals are antagonistic. The first seeks to maximize line productivity, which means minimizing the load on the busiest workstation. The second aims to maximize line robustness, expressed by a specific measure, and lies in the potential presence of tasks with uncertain processing time. A reconfigurable environment enables an already provided assembly line balancing (or LB) to adjust or improve its level of productivity or robustness if necessary, by allocating extra resources to workstations. As their number is limited, it is important to use them as efficiently as possible, and therefore to keep only such allocations, called efficient reconfigurations (or ER), which are non-dominated in the Pareto sense for two objectives studied. Different LB options provide different varieties of ER. In order to compare them, we introduce the so-called measure of scalability, which is computed into two steps. At first, for each set of ER sharing the same number of used extra resources, the hyper-volume of the image of this set in the objective space is calculated. Then, the sum of all these hyper-volumes is viewed as the scalability measure for the studied LB. To find an LB with the greatest value of its scalability measure, a simulated annealing is developed and tested on instances of different size.

4 - Scheduling ULD loading operations in air cargo hubs

Ricardo Euler, Ralf Borndörfer, Christian Puchert, Tuomo Takkula

Air cargo typically moves through airports that serve as hubs. A container or pallet, usually referred to as a unit load device (ULD), arriving at such a hub often holds shipments bound for various destinations. Consequently, its contents must be unloaded and moved into storage (ULD break-down). Once enough shipments for a single destination have accumulated, a new outbound ULD is loaded (ULD build-up). Both the build-up and break-down procedures need to be executed on a limited number of workstations and within the strict timeframe dictated by the flight schedule. Resource conflicts, therefore, need to be prevented by a careful scheduling of build-up and break-down processes.

We explore the structure and challenges of these interdependent scheduling problems, both from a mathematical and industry viewpoint, and discuss appropriate solution strategies. We find that break-down scheduling is easily solved by simple mixed-integer programming (MIP) models on realistic datasets. The situation differs for build-up scheduling, where a desire to build up ULDs in batches introduces an additional objective. Here, we discuss a tailored approach based on logic-based Benders decomposition that decomposes the time horizon based on cargo availability. Finally, we discuss how to integrate

both break-down and build-up scheduling into a unified network design model.

Location in Logistics and Supply Chain Management

Stream: Locational Analysis

Invited session

Chair: *Giuseppe Bruno*

1 - From isolated core facilities to interrelated service regions: understanding dependencies in supply chain network design

Hannah Bakker, Stefan Nickel

In supply chain network design (SCND), facility location decisions play a pivotal role. Yet, the individual role of and interdependence between facilities constituting an optimal solution remain inadequately understood. This lack of contextual information hinders decision-makers' confidence in these models, resulting in a gap between academic research and practical implementation. Our study evaluates optimal and near-optimal solutions for a given instance, introducing concise measures to characterize commonalities in the decisions and the criticality and interdependence between individual location decisions. We relate these characteristics to the spatial distribution of candidates and customers and show that contrasting academic perception, the underlying spatial patterns yield little explanatory value for the stability of location decisions. We propose a pattern-recognition-based approach to show that well-performing solutions to an instance often share an implied division of the facility customer space, which not only explains the criticality and relationship between individual facilities but also allows anticipating how minor perturbations will affect the network. Our research offers a deeper understanding of facility location dynamics within SCND. This may empower decision-makers to trust and implement these models in real-world settings.

2 - Integrating location and inventory decisions in healthcare supply chains: review and first model

Inez Puttemans, Kris Braekers, An Caris

Healthcare institutions, including hospitals and retirement homes, face various challenges. They struggle with tight budgets due to government savings and rising costs. Moreover, they deal with a shortage of care staff due to high workloads, forcing them to make an effort to relieve non-care tasks (i.e., logistics tasks). These challenges put significant pressure on healthcare institutions. To address these challenges, hospitals aim to reduce costs and improve healthcare logistics while ensuring high-quality care. One key opportunity to improve healthcare logistics is consolidating inventory across healthcare institutions. This entails healthcare institutions within a network pooling their inventory from individual warehouses into one or a few central care hubs. Decision support for inventory pooling is facilitated by integrated decision-making on location and inventory. Adopting this integrated decision-making can cut costs and enhance healthcare logistics while at least maintaining quality of service. This research aims to develop innovative models and solution algorithms, providing decision support to improve healthcare logistics by integrating location and inventory decisions. This talk will discuss key findings from a new literature review on integrating these decisions, covering 44 papers across contexts like manufacturing, healthcare, spare parts, etc. Moreover, a first mathematical model focusing on integrating these decisions in a healthcare context will be proposed.

3 - Dynamic spaces in layout planning - a new concept to introduce time-dependent layouts

Niklas Braun, Rebekka Volk, Frank Schultmann

Current dynamic layout models only consider changes in the placement of temporary facilities, like workstations and material storages, without considering changes in the spatial structure of the layout itself. While they are practical to account for repositioning of the facilities and the resulting changing material flows, these models assume a static layout structure over time. To address this limitation, we present a novel optimization model introducing 'dynamic spaces'. They accommodate the changing availability of rooms or areas representing the layout over time. This innovation finds application in many cases, such as optimizing deconstruction projects where parts of a building are taken down and can't be used as locations anymore midway through the project or when safety protocols require certain areas of a factory to be sealed off temporarily during remodeling. Additionally, it can also be used to represent expanding layouts e.g., if surrounding areas are temporarily used during a construction project. In this contribution we analyze the difference in the optimization process compared to classical formulation and show the strength of the new model in numerical case studies.

4 - Strategies for the redefinition of postal collection and delivery services in urban areas

Giuseppe Bruno, Antonio Diglio, Carmela Piccolo, Eduardo Pipicelli

The rapid increase in the volume of parcels to be delivered pushed logistics providers to explore innovative solutions to streamline the more critical and expansive stage of the supply chain: the last-mile logistics. Among the solutions, the most explored is self-collection, by which customers autonomously collect parcels from manned or unmanned facilities. However, the success of the strategy depends on two main aspects: the individuation of the determinants affecting the customers' choices; the location of such facilities in relation to the positions of the potential customers.

In this work, we explore the possibility of describing these aspects through the formulation of mathematical models for the optimal location of self-collection facilities with the objective of maximizing the attractiveness of this system, as alternative to home delivery. In particular, the mechanism of patronization of potential facilities is regulated by an attractiveness function in which some determinants are considered.

Thanks to the cooperation with the principal Italian logistics provider, we apply the model to some real case studies with the objective of designing efficient and robust self-collection networks in densely populated contexts. The obtained results suggest insightful managerial implications and prove that the model can be used as an appropriate tool to support the decision-making process concerning the design of a self-collection network in an urban context.

empty containers between ports in multiple time periods is challenging. In this paper, we consider two neighbouring ports that are facing independent and uncertain supply and demand of empty containers from shippers. We seek the optimal empty container transfer policy between two ports over a multi-period planning horizon to minimize the total expected cost, consisting of empty container transferring costs between two ports, inventory holding costs, and container leasing costs at both depots. The problem is formulated as a stochastic dynamic programming model. The local properties of the value function, such as the first and second derivatives on a region-wise basis, are analysed. The region-wise properties of the value function enable us to establish the structural characteristics of the optimal empty container transfer policy over multiple time periods. Specifically, the entire state space is divided into three control regions by two monotonic switching curves. The asymptotic behaviours of the switching curves are analysed analytically. The structural properties of the optimal policy and the asymptotic behaviours of the switching curves are then used to construct simple near-optimal and easy-to-operate policies. Numerical examples are provided to demonstrate the analytical results.

2 - HafenPlanZen - Port Master Planning through Simulation, Optimization, and Visualization

Larissa Timm

Maritime transport is vital to global trade, with ships carrying over 80% of the world's goods in volume. Efficient port planning is critical to the functioning of intermodal hubs like the Port of Hamburg, but long concessions of 20-30 years make port planning a complex and challenging task. A port is constantly evolving due to technological, economic, political, and environmental factors, requiring innovative approaches to port planning. Our project, HafenplanZen, is funded by the IHATEC program and is a collaborative effort between the Hamburg Port Authority, Hamburg Port Consulting, and the University of Hamburg. The Port of Hamburg already has a high degree of digitalization and employs multiple digital twins to simulate and optimize various aspects of port operations. HafenplanZen leverages this digital infrastructure and serves as a support tool for port planners, integrating data from multiple digital twins to provide a comprehensive overview of the port's behavior and efficiency. One of the project's key focuses is the development of a sophisticated 3D visualization tool that uses simulation to evaluate the port's performance. HafenplanZen's simulation-based approach enables port planners to test various improvement strategies and make informed decisions about optimizing port performance. The tool also provides improvement suggestions based on simulation results, allowing planners to make data-driven decisions about how to improve the efficiency of port operations.

3 - A Simulation-Based Optimization Framework for Adaptive Disruption Management Strategies in Synchronal Transport

Mahnam Saeednia, Saiedeh Razavi, Bilge Atasoy, Siyavash Filom, Muhammad Satrya Dewantara

Disruptions that impact transport operations are an inevitable reality that pose significant challenges. These disturbances, escalating in both frequency and impact, have far-reaching implications on seamless freight transport operations. From unexpected weather conditions to unplanned maintenance of the transport network, each disruption brings with it a ripple effect that can drastically alter the planned movement of freight. This, not only negatively impacts the immediate transport operations but also has profound implications on the broader supply chain landscape, necessitating innovative solutions to ensure resilience and reliability. This paper proposes a simulation-based optimization framework for adaptive disruption management strategies. It incorporates real-time events dynamically to facilitate selection of modes, routes, and handling points. It leverages an event-based model to capture the dynamics of the system at the event of a disruption. The stochastic optimisation model lying at its core generates disruption-aware reactive solutions to minimize their potential impact. These solutions are informed by optimal disruption management policies such as rerouting, transshipment, or holding, thus ensuring enhanced operational resilience and efficacy in response to disruptions. This adaptive approach to disruption management facilitates more resilient, robust, efficient, and sustainable supply chain operations in the face of increasing uncertainties and disruptions.

4 - Port-hinterland transport: addressing sustainability with cooperation and electric trucks

Claudia Caballini, Erika Olivari, Simona Sacone, Mahnam Saeednia

Vehicle electrification represents one of the most promising solutions to significantly reduce road transport emissions, paying attention to the full energy cycle. However, truck electrification has downsides such as economic investments, limited battery life and charging time requirements. Cooperation is another lever for increasing sustainability: sharing transport orders allows the reduction of the number of trucks needed to meet the transport demand, resulting in increased profits and reduced CO2 emissions. This paper proposes an optimization model for the cooperative planning of road transport operations, matching trips owned by different carriers and assigning them to a fleet of diesel and electric trucks. The final objective is to maximize the total carriers' profit while reducing emission costs. Time windows, haulers' driving constraints, maximum duration of electric batteries, charging times and emissions costs are considered. A compensation mechanism is introduced to motivate carriers to share their trips. The problem is solved using exact approaches and evaluated using a real data-set related to the port of Genoa and its hinterland. An experimental campaign is carried out, making sensitivity analysis on some significant factors of the problem. A numerical analysis is realized to evaluate the computational effort necessary to solve large-size case studies and an appropriate heuristic approach is designed for large problem instances.

New Challenges for Risk Management

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: Mariacristina Uberti

Chair: *Simone Landini*

1 - The estimation risk under the IRB approach: an analytic way-out

Simone Casellina, Simone Landini, Mariacristina Uberti, Patrick Zoi

The Internal-Ratings Based (IRB) approach is aimed at providing a measure of the maximum loss that a credit portfolio could generate over a year and with a given confidence level. As most of the standard risk measures, such as the Value-at-Risk (VaR), or the Expected Shortfall (ES), also the IRB measure depends on some parameters that must be estimated. The usual plug-in approach, consisting in substituting in the theoretical formulas the parameters with their estimates, does not consider the effect of the additional uncertainty generated by the estimation error. In this paper, we develop an analytical correction to the IRB formula that enables us to correct for the parameters uncertainty, using the theoretical setting developed by Gouriéroux and Zakoïan (2013) and, to our knowledge, this is the first application of that approach to credit risk. This approach provides an approximated correction that depends on the variance-covariance matrix of the estimated parameters and does not require specific assumptions on their prior distribution, avoiding also computationally intensive Monte Carlo simulations. We show the validity of our correction on simulated data and show that our results are consistent with Tarashev (2010) who adopts Bayesian methods. We argue that our approach is more flexible and suited to be extended to the estimation of other parameters of the IRB formula. We show a practical application of our approach relying on real data.

2 - Financing the circular economy: effects on bank risk management

Nadia Ricci, Caterina Lucarelli, Pietro Vozzella

The circular economy encourages a move away from the traditional linear corporate approach to production and consumption in favor of integrated systems with external connections and in which materials circulate in a closed circular loop leading to substantial improvements in resource efficiency, energy savings and achievement of sustainability goals. In this transitional process, access to bank financing for firms is a key challenge not only in the perspective of circular businesses but also in the perspective of banks which must consider new factors that may influence the creditworthiness evaluation process with an impact on risk management. Consequently, circular businesses and banks are linked in a new systemic and complex approach both in practice and in academic literature. The aim of this research is to explore this twofold area and understand its main characteristics in order to develop future research on this topic. To achieve this objective we developed a conceptual framework that guided a literature review based on a selection of 42 articles explored through a bibliometric and thematic analysis. Our results confirm the complexity of the relationship between circular businesses and banks: in the implementation process circular businesses are mainly faced with financial barriers; banks do not consider the impact of circularity factors in assessing credit risk and default probability of circular businesses; there is a need for banks to shift from a shareholder vision.

3 - Evolution of IRB models through new data sources and machine learning

Federico Avataneo

The data available on SMEs (small and medium-sized enterprises) has recently experienced a sharp increase as new sources have emerged, providing value added to improve the risk management models of banks, which can be processed using advanced ML techniques. The characteristics of this segment make the adoption of ML models particularly well-suited and strategic, supporting process automation and digitalisation. To achieve these goals, the rating model has been updated, making it available online and in real time, without easing risk management standards. ML algorithms provide a tool to complement pre-existing approaches enhancing their breadth and accuracy.

4 - On the Adverse Selection in longevity risk Transfer

Valeria D Amato, Maria Carannante, Massimiliano Menziotti, Steven Haberman

The literature finds evidences of adverse selection all insurance businesses. Nevertheless, these analyses remain inconclusive as regards the economic consequences for the insurance industry, particularly for institutions bearing longevity by transferring the longevity risk exposure. The present research gives a contribution to the assessment of the adverse selection in the context under consideration and evaluate the change in the cost of transferring longevity to capital market, which can be pointed out as a sort safety loading, consisting in an optimal hedge, i.e. "the equilibrium hedge", since it contains the market inefficiencies due to the adverse selection effects. For estimating the longevity exposure, the projections are based on a more informative stochastic model which is the frailty-based model proposed by the authors.

Dynamic Vehicle Routing 2

Stream: VeRoLog - Vehicle Routing and Logistics

Invited session

Chair: Pirmin Fontaine

1 - Dynamic Routing Problem With Time Windows in a Signalized Road Network

Yi-Fen Huang, Tsung-Sheng Chang, Yen-Yu Chen

The ability to guide vehicles through the best routes to their destinations according to dynamic traffic information is called for in transportation and logistics operations. However, it is well known that the dynamic routing problem is very difficult to tackle due to dynamic nature of road networks, traffic evolution, and time-sensitive delivery constraints. It is noted that existing route planning methods often fail to adapt to non-recurrent traffic congestion and especially unexpected events such as accidents. That is, effective route planning methods must be equipped with dynamic strategies for dynamic adaptation to traffic changes. Therefore, our research intends to develop a dynamic route planning method by leveraging dynamic traffic data and predictive modeling techniques. More specially, this method timely adjusts vehicle routes based on changing traffic conditions and time constraints. Note that the proposed dynamic route planning method focuses on signalized urban road networks. We use simulation technique to verify the proposed method and carry out sensitivity analysis.

2 - Multi-Trip Vehicle Routing Problem With Multiple Time Windows and Dynamic Starting Locations

Evren Guney

Vehicle Routing Problem with Time Windows (VRPTW) is a well-studied challenging combinatorial optimization problem. In this work, we focus on an extension of VRPTW where each vehicle can travel multiple routes, each customer has multiple time windows and each vehicle can start their route from their latest destinations. These kind of problems usually arise in marine routing problems, where a fleet of ships need to visit multiple customer and supplier ports and the trip may end up in any of the ports. Then, their next trip will start in the last port they have visited in their previous trip. Usually the optimization problem is defined over a planning horizon, however the routing scheme and the initial/final locations of the ships are dynamic depending on the planning horizon cut-off dates.

A mixed integer linear programming formulation is developed to represent the problem and various small-sized instances are solved exactly, using commercial solvers. For larger instances various heuristic and meta-heuristic methods are being developed and tested.

3 - Dynamic Location-Routing With Modular Production Facilities and Resource Collection: A Variable Neighborhood Search Approach

Julia Erdmann, Tristan Becker

In the transition to climate neutrality, hydrogen is expected to play a vital role as a clean and versatile energy carrier. However, large-scale deployment of hydrogen requires adequate production and transportation infrastructure. A promising option to produce renewable hydrogen involves the utilization of biomass gasification. To efficiently bridge local biomass potentials and hydrogen demand, decentralized, small-scale production networks with mobile production units present an opportunity. In this context, we recognize a new optimization problem that integrates the dynamic location-routing problem with the traveling purchaser problem, accounting for relocatable modular production facilities. We propose a novel integer programming formulation, considering resource management, production, transportation, and demand fulfillment. To address the computational challenges arising from practical applications, we develop a Variable Neighborhood Search (VNS) heuristic, which consists of sequentially optimizing location-allocation, resource selection, and routing aspects, using multiple neighborhood structures and random perturbation strategies. Extensive computational experiments illustrate the effectiveness of our VNS approach across a large set of problem instances. Furthermore, we present a case study focusing on local biomass-to-hydrogen production in Germany, leveraging straw as a feedstock and demonstrating the practical applicability of our proposed methodology.

4 - A Supervised Machine Learning Framework to Predict the Request Fit for Dynamic Dial-a-Ride Problems

Pirmin Fontaine, Simon Mader, Stefan Voigt

In the transformation towards sustainable transportation, a good public transport offer is a crucial element. However, in rural areas, public transport providers (PTPs) face challenges in introducing a good offer using classical line-based services within a restricted budget due

to the low demand. One potential solution is on-demand buses, which operate on flexible schedules and routes that depend on the actual demand. Still, the low demand in these regions remains a challenge to PTPs. They want to maximize the served passengers but are forced to accept or reject customer requests immediately within the dynamic booking process and without knowing the true impact of the total number of served passengers due to potential future requests. This raises the question of predicting the customer's fit within a passenger maximizing dial-a-ride problem (PM-DARP).

To address this problem, we introduce the request fit predictor (RFP) framework that allows for fast decisions about the acceptance or rejection of customer requests. Within this framework, we model the request fit as a binary classification task and learn the fit with supervised machine-learning models from a static PM-DARP using historical data.

The framework is tested on real-life data, and the results show that the PTP can serve 7.48% more passengers using the RFP compared to a cheapest insertion benchmark and more than 25% more than the status quo. As a side effect, we also reduce the driven distance by 6.68%.

The fusion of machine learning and optimization has the potential to deliver outcomes for engineering applications that the two technologies cannot achieve independently. This talk illustrates this potential with the concept of an optimization proxy that can produce, in real time, feasible and near-optimal solutions to classes of optimization problems. The talk reviews the theoretical foundations underlying optimization proxies and demonstrates its practical practical on applications in power systems, supply chains, and mobility.

1 - Optimality and fairness in kidney exchange programmes

Péter Biró

In this talk we survey some recent developments on the OR aspects of kidney exchange programmes (KEPs). These programmes have been established in most of the Western countries in the last two decades to facilitate the exchange of living kidney donors for those recipients who have willing but immunologically incompatible donors. In the first part, we describe the European practices including the hierarchic optimisation used in the matching runs of the KEPs for computing optimal solutions. These IP-based methods have been implemented in the simulator software developed in the ENCKEP COST Action (2016-2021) and subsequently incorporated in the KEPSOFT software that provides a common IT-platform for European applications. In the second part, we describe an alternative solution concept based on the individual fairness notion of stability. We explain how this classical cooperative game theoretical concept can incentivise the recipients to register valuable donors or multiple donors in KEPs. Finally, in the third part, we present new results on international KEPs, where credit-based compensation schemes have been proposed to balance out the benefits of the countries when merging their national pools.

New Advances in Italian Energy Markets

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: Cristian Pelizzari

1 - Is storage a business? A test on the Italian day-ahead electricity market

Stefano Zedda, Simone Sbaraglia, Alessandro Fiori Maccioni

Energy storage systems emerge as key elements in optimizing sustainable resource use, ensuring a steady flow of energy even when primary sources, such as sun or wind, are intermittent. In this scenario, the techno-economic integration of storage technologies becomes a key building block in the transition to a more resilient and efficient energy system. In this paper, we considered the possibility of using the electricity storage as a business, buying electric energy from the Italian electric day-ahead market when prices are low, and selling it back when prices are high. The theoretical modeling and the resulting simulations show that the storage can actually be a profitable business, and that its results are highly variable over time. In particular, the recent gas prices crisis changed the framework, showing very interesting revenue opportunities.

2 - Optimizing hydro-pumping plants management in the new storage market

Diana Tratta, Paolo Falbo, Carlo Filippi

The high short-term volatility of renewable energies raises supply security issues that can be addressed through energy storage technologies. The idea of introducing a long term energy storage market is the solution for two problems in the investment of storage technologies: high costs and high volatility of energy prices. The main goal of this paper is the modeling and solution of a profit maximization problem for a risk-averse energy producer, who owns an hydroelectric pumping storage facility, and aims to seize the opportunity to finance the investment through an energy storage market. We modeled the facility owner's decisions through an optimization problem. The owner profits from both selling storage capacity to a counterpart and participating in speculation within the energy spot markets and ancillary services. Our contribution to literature lies in the joint optimization of generation/pumping and the decision sell part of the storage capacity. One of the main profit opportunities for the plant owner is to fulfill customer orders through accounting rather than physically. This introduces a significant complication: it is necessary to consider water movements from both an accounting and a physical perspective. The decision maker risk's aversion has been formulated including the Conditional Value-Risk as a risk measurement in the objective function.

3 - Efficient Incentive Policies of Renewable Energy Communities

Alessandra Ruffini, Paolo Falbo, Carlos Ruiz

In 2018, the EU issued a Directive on Renewable Energy Communities (REC). REC implementation will increase RES-based electricity supply and decrease GHG emissions. National Governments are financing ecological transition with incentives, and a relevant amount of funds is reserved for REC. Anyway, the success of these investments depends on people's, firms' and municipalities' choice to join a REC. A direct economic advantage of joining a REC is that members can share an incentive tariff calculated on self-produced and self-consumed electricity. In our work, we face the problem of maximizing self-consumption to promote RECs diffusion. For this purpose, we develop a bi-level problem with a policymaker and one REC. We consider a particular kind of REC composed of households (HS), that can install photovoltaic plants (PV), and a biogas plant (BG), because these are the most common technologies in agricultural and urban contexts. At the upper level, the central authority maximizes REC's self-consumption by financing investment in RES plants. At the lower level, the BG and HS interact in the same REC, maximizing their profits subject to capacity and budget constraints. We developed two versions of this model to have results independent from the iteration order and to reach a Nash Equilibrium. Results are obtained through historical scenario simulation using Italy's data from 2017 to 2021 and developed in Pyomo with Gurobi Optimizer.

1 - Integration of Operations Research (OR) and Machine Learning (ML) - A Literature Review

Francis Miranda

There is an increasing trend of combining Operations Research (OR) with Machine Learning (ML) techniques. Both disciplines are already very beneficial when used independently. Combining both techniques will even enhance the benefits. The author starts with a brief historical overview on Operations Research (OR) and Machine Learning (ML), tracing the important milestones in each field. Then the author talks

about the different categories and techniques used in Operations Research and Machine Learning, highlighting the diverse methodologies such as linear programming, mixed integer programming and network optimization in OR, together with supervised, unsupervised learning and reinforcement learning in ML. Next, the author talks about the practice of Operations Research and Machine Learning, including the educational background and job roles or functions of practitioners in the field, the software tools and the most common techniques or algorithms used. The author also discusses the different applications in various industries. The author will highlight the benefits and limitations of Operations Research (OR) and Machine Learning (ML) when used independently. Then, the author explores the ways both techniques are integrated based on the literature such using ML then OR, using ML in OR, and using OR in ML. Finally, the author will mention some case studies from the literature how companies leveraged on both techniques to enhance their operational decision-making process.

2 - Optimizing Post-Disaster Recovery Strategies in Telecommunication Network Infrastructure

Mohamed Saâd El Harrab, Michel Nakhla

In the wake of an increasing number of natural disasters such as storms and cyclones, overhead electricity and telecommunications infrastructures are exposed to significant risks, with damage to pylons, antennas and poles disrupting essential services.

This study introduces a hybrid model that integrates machine learning and discrete optimization to optimize emergency response. By analyzing storm damage to electricity and telecoms networks, we apply machine learning to cluster affected areas based on storm severity, customer reports and wind speed. This data-driven insight informs a unique mixed-integer programming model, treating the challenge as a variant of the capacity expert routing problem. Our solution employs computational experiments and the Branch and Price algorithm, with a detailed case study of a storm event in France serving as a practical illustration.

The results demonstrate the effectiveness of our hybrid approach in optimizing emergency team deployment strategies, adapted to the varying requirements of different storm severities. This contribution enriches the emergency operations management and disaster relief domain, presenting a novel perspective on combinatorial optimization for crisis mitigation.

3 - Unit Commitment Predictor

Farzaneh Pourahmadi

The system operators usually need to solve large-scale unit commitment problems within limited time frame for computation. In this talk, we will discuss how by learning and predicting the on/off commitment decisions of conventional units, there is a potential for system operators to speed up their computation significantly. Additionally, we propose a data-driven unit commitment model enabling the system operator to utilize available contextual information in the unit commitment model to enhance decision-making efficiency. We explore whether, and if so to what extent, our proposed data-driven model outperforms stochastic models.

4 - Rise of Conscious Consumers: Impacts of Corporate Workplace Equality on Household Spending

Chang Liu

We first construct a measure of corporate workplace equality based on textual analysis of equal employment opportunity (EEO) statements in online job postings. We validate this measure by demonstrating its predictive power for future employment discrimination lawsuits and identifying the costs that deter low-equality firms from mimicking high-equality peers. We then show a positive correlation between corporate workplace equality and consumer spending and propose two economic channels: preference and innovation. To establish the preference channel, we demonstrate that the correlation between corporate workplace equality and consumer spending increases when consumer preferences experience exogenous shocks in major social events, such as the MeToo Movement in 2017 and the Black Lives Matter Movement in 2020. This effect is particularly strong among gender and

racial minority groups. To establish the innovation channel, we demonstrate a higher correlation between corporate workplace equality and consumer spending among more innovative industries and show that corporate workforce equality can predict innovation efficiency in terms of patent quantity, quality, originality, and generality.

Algorithms for Mixed-Integer Nonlinear Programming and Nonconvex Optimization

Stream: MINLP

Invited session

Chair: Jan Kronqvist

1 - Warm Starting of Outer Approximation for Biobjective MINLPs

Erik Tamm, Jan Kronqvist

Multiobjective mixed-integer nonlinear programming is a challenging type of problem to solve even when the continuous relaxation is convex. This work presents two new methods which attempt to solve convex biobjective MINLPs efficiently. This is done by considering the so-called epsilon-constraint method for a biobjective problem. Since the set of nondominated points is in general not convex due to integrality constraints, the classic weighted sum method is not suitable. The epsilon-constraint method solves a sequence of similar convex MINLPs to approximate the set of nondominated points. Each subproblem can be solved using outer approximation, where a polyhedral approximation is obtained. The main contribution of the work is the two methods presented of how to reuse the polyhedral approximation from a solved subproblem when solving the next one. The methods are derived from two observations. First, the subproblems are by construction increasingly restrictive, which means that a valid cut will be valid for all the following subproblems. Second, the problems are only slightly changed, which means that the integer combinations needed to be visited should be similar between subproblems. Preliminary results show that there is a noticeable improvement in both solution time and the number of iterations needed to solve each subproblem.

2 - Mixed-Integer Semidefinite Programming by Outer Approximation

Jan Kronqvist

We consider different methods for generating cuts and solving mixed-integer semidefinite programming (MISDP) instances within an outer approximation framework. In fact, the main components of the classical outer approximation algorithm for convex mixed-integer nonlinear programming can easily be tailored towards MISDP such that similar convergence properties are obtained. We propose some new methods for generating cuts that have desirable theoretical and computational properties and we present a numerical comparison.

3 - Generating cuts with phantom branching

Yehor Blokhin, Jan Kronqvist

We consider a strategy for generating cuts for set partitioning and set packing constraints. We perform an exploitative wide branching to detect infeasible and suboptimal integer combinations and tighten continuous relaxation. The idea originates from results that even restarting branch-and-bound solver can be beneficial for overall performance.

4 - Polynomial Optimization: Tightening branch-and-bound schemes with conic constraints

Brais González Rodríguez, Raúl Alvite Pazó, Samuel Alvite Pazó, Bissan Ghaddar, Julio González-Díaz

Conic optimization has recently emerged as a powerful tool for designing tractable and guaranteed algorithms for non-convex polynomial optimization problems. On the one hand, tractability is crucial for efficiently solving large-scale problems and, on the other hand, strong bounds are needed to ensure high-quality solutions. In this research, we consider constraints based on linear, second-order cone, and semidefinite programming and study their impact when used to tighten the baseline relaxations of a given global optimization algorithm. We describe how to design these conic constraints and their performance with respect to each other and with respect to the standard RLT relaxations for polynomial optimization problems. Our finding is that the different variants of nonlinear constraints (second-order cone and semidefinite) are the best performing ones in around 50% of the instances in widely used test sets. Additionally, we present a machine learning approach to decide on the most suitable constraints to add to a given instance. The computational results show that the machine learning approach significantly outperforms each of the individual approaches.

Chair: Gerhard-Wilhelm Weber

1 - Applying multiple indicators to assess the relationship between finance and human factors

Betül Kalaycı

There are various empirical phenomena relating to individual investors' behavior, such as how their emotions and opinions influence their choices. Sentiment refers to all of these emotions and opinions. In finance, stochastic changes can occur in response to investor sentiment levels. Machine Learning methods are well-known and helpful tools for prediction problems, and they have already been applied successfully to handle a wide range of financial problems. In this study, we focus on the behavior of financial difficulties based on the sentiment levels of investors, rather than pure financial problems. The goal of this study is to evaluate sentiment index prediction performance using two-stage MARS-NN, MARS-RF, RF-MARS, RF-NN, NN-MARS, and NN-RF hybrid models. We further prepare to describe people's sentiments toward the economy according to their level of confidence. For this objective, we employ HMM to estimate the underlying state change of the Consumer Confidence Index (CCI) and investigate its relationship with some macroeconomic indices (CPI, GDP, and currency rate) at monthly intervals. The purpose is to monitor and comprehend the transitions between these phases, as well as to chart a course through them. We also plan to apply volatility models to each subgroup we receive in HMM to see if we can improve our predicting results.

2 - Identifying high-risk job advertisements on social media to help mitigate labour exploitation.

Preeti Sharma, Mahnaz Hosseinzadeh, Sajid Siraj

Millions of individuals are subjected to exploitative labour practices worldwide. This project focusses on intervention at the recruitment stage, where deceptive job advertisements often proliferate unchecked. We propose a machine learning approach to identify high-risk online job adverts potentially leading to labour exploitation. With the help of natural language processing techniques such as word embeddings, we extract relevant features from a sample of job adverts, obtained in

collaboration with a non-profit organisation. Using these features, we then train a predictive model to distinguish high-risk adverts from others. We validate our model using a different set of job adverts which are unseen to the model. Through this work we demonstrate the use of machine learning to help vulnerable job seekers by facilitating timely intervention. This work represents a crucial step towards mitigating the risk of labour exploitation in the digital age and safeguarding the rights of workers.

3 - Employing artificial intelligence in healthcare: a systematic approach for the detection of mental disorders via social media analysis

Qing Yin, Yunya Song, Xian Yang

The rising prevalence of mental disorders significantly strains public healthcare services. The rapid growth of social media has created a solid foundation for research into public mental health. Artificial Intelligence (AI)-assisted methods have been developed to detect mental disorders in social media posts. However, existing studies have primarily focused on a limited array of predefined mental disorders, overlooking the continuous emergence of unknown mental disorders. This study presents an innovative method by establishing a comprehensive system based on pre-trained language models (PLMs), termed as systematic PLMs (sPLMs). This system is adept at detecting known/in-domain (IND) and unknown/out-of-domain (OOD) mental disorders, and it further specifies the names of the mental disorders detected. Comprehensive experimental assessments in a public social media dataset, the Reddit dataset, demonstrate that sPLMs outperform pure PLMs (pPLMs) in detecting OOD mental disorders, achieving a 16.54% higher average F1 score. Furthermore, sPLMs exhibit a 91.58% accuracy in generating names for OOD mental disorders. This superior performance, both quantitatively and qualitatively, paving the way for advanced AI applications in healthcare domain.

4 - Stochastic scheduling in the presence of side data - case: surgery planning

Ricardo Otero, Erik Demeulemeester

In this research, we focus on the stochastic Advance Scheduling Problem with Downstream Capacity Constraints (ASPDCC) in the case where the decision maker has access to side data. We begin formulating the stochastic ASPDCC as a two-stage stochastic program using a sample average approximation (SAA) approach. Unlike the common method to characterize uncertainty, which assumes a lognormal distribution as the true data-generating process for each surgical specialty, we propose a data-driven framework that integrates a machine learning algorithm (decision trees) to estimate the conditional probability distribution for the surgery durations and the length of stay (LoS), in the presence of side data. Finally, to speed up the solution of the SAA model, we use a benders decomposition incorporated into a branch-and-cut framework. To justify the value of using side data, we perform extensive experimentation using real data from a reference hospital in Bogota, Colombia. Results show that our algorithm generates schedules that outperform the traditional method of fitting a lognormal distribution for each surgery specialty.

Behaviour and decision processes

Stream: Behavioural OR

Invited session

Chair: Ilkka Leppanen

1 - Robust determination of certainty equivalents

Bernhard Nietert

Certainty equivalents are a core concept in Finance/Economics. Nevertheless, their experimental detection as outlined in papers like Holt/Laury (2002) and ensuing publications is not robust and not reliable enough given its role as a core concept: it consists of a one-off

choice between a risky lottery and a riskless payoff and does not consider further conditions that might exert influence. For that reason, this paper uses on the one hand the PEST procedure advocated by Luce. PEST analyzes repeated (and not just one-off) choices and determines certainty equivalents from the steady state, i.e., when decision makers no longer switch between the riskless payoff and the risky lottery. On the other hand, conditions are specified as: (i) expected value is given as additional information next to the state-dependent outcomes of the risky lottery; (ii) different starting values of the riskless payoff in PEST. This paper finds: (i) The condition "expected value" leads to higher average reaction times and requires more trials in the PEST procedure compared to the benchmark case "only state-dependent outcomes". (ii) The starting value of the riskless payoff in the PEST procedure exerts massive influence on certainty equivalents. (iii) The number of fixation points (derived from eye tracking) and reactions times can (partially) explain why conditions influence certainty equivalents.

2 - Process tracing and attention in preferential choice

Ilkka Leppanen

Decision making among options that consist of many attributes or that contain risk is commonplace in various everyday contexts, and understanding how these decisions are made is highly valuable for researchers and practitioners. Here I develop scroll tracking, a novel process tracing method that builds on a simple mobile web application where the decision maker scrolls between options and the app tracks their response dynamics in pixel-time coordinate space. I then use scroll data obtained from two studies, a consumer choice problem and an risky decision making problem, to study predictions made by different attentional evidence accumulation models. The information obtained from the app can be used to successfully predict different attention-choice relationships and to predict subjective value. I also compare several evidence accumulation models, equipped with the scroll data, in their predictive ability. All the models are able to benefit from the rich variety of data that scroll tracking provides. These findings demonstrate the potential of novel, naturalistic process tracing tools that can be used to covertly study latent decision processes.

3 - How, when and why human agents act in a simulation? The PRIAGE architecture.

Miguel Baigorri, Fermin Mallor

Modeling human behavior is a highly complex task because humans don't always act rationally, and their actions can be influenced by a wide variety of stimuli that are difficult to measure. However, accurately modeling human behavior is one of the main challenges in developing useful agent-based simulations that can be applied to real-life situations. We propose a new architecture called PRIAGE (Pursued, Requested, and Induced Actions for reaching Goals in the Environment), which offers an innovative approach to the influence of an agent's internal state on their actions. In the majority of existing human-behavior paradigms the agent's internal state is used only to determine which action to choose from a set of possible actions. PRIAGE focuses on describing the different reasons that can trigger an action: agents' actions are either requested by the environment, induced by the agent's internal state, or actively executed by the agent to achieve goals. A second novelty is that the internal state is not only used to determine what action to do next, but may also influence how well the action is performed, creating performance measures that can modify the environment and the agent. After describing the new proposed architecture, we apply it to a case study analyzing physicians in an emergency department. We focus on how the internal state of the agent influences two performance measures: the treatment time and treatment quality of patients.

4 - The effect of customer priority and planning complexity on deviations from model-generated recommendations in route planning

Marieh Kadivar, Sarah Gelper, Tom van Woensel

Despite the significant advancements in optimization models for route planning and their implementation in planning tools, planners often deviate from the recommended solutions offered by these tools. To detect the factors that influence such deviations, we analysed field data

obtained from six small-sized transportation companies in the Netherlands. A meta-analysis across these companies suggests that (i) the prioritization of important customers and (ii) the level of complexity of the planning problems affect the extent to which planners deviate from the recommended routes. Planners learn which customers are more important using customers' history of orders and take that into consideration in route planning. However, the impact of customer priority on routing decisions varies depending on the complexity of the planning task. Planners increasingly adhere to the recommended routes when faced with more complex routing problems. This can possibly be explained by the fact that prioritizing important customers, and simultaneously minimizing the distance of the route, requires more cognitive load. As a result, planners deviate less from the tool's recommendations for complex routing problems, even when such routes serve a high number of important customers.

Theory of Knowledge, Technology, and Innovation

Stream: Knowledge, Technology, and Innovation

Invited session

Chair: A. D. Amar

Chair: Santanu Roy

1 - Supplier reputation and Supplier-sourced innovative new technologies adoption

Rupak Rauniar, Steve Zhou

Rooted in the theories of transaction cost economics and contingency theory for technology transfer, this study is being undertaken to examine supplier reputation aligned with the competitive needs of an organization as an important criterion for the selection of supplier-sourced innovative new technologies. Competitive advantage for an organization through supplier-sourced innovative technologies would be empirically investigated by i) analyzing the relationship of supplier reputation fit with the competitive advantage of the organization, and ii) analyzing the relationship between competitive advantage and the successful adoption of supplier-sourced innovative technology in the organization. As such, the study aims to make an important theoretical contribution in the area of buyer-supplier innovative technology diffusion, transfer, and integration. Further, as more organizations are undertaking digital transformation initiatives, the proposed study can provide empirical evidence for the managers on the importance of supplier reputation as a critical selection criterion for supplier-sourced innovative new technology.

2 - Cutting off the offcuts

Arti Amar, Jim Bamford, Will Gibson, Simon Barrans

This paper describes a case study of the application of Lean Thinking in a Small-Medium Size(SME) manufacturing industry. Associated Utility Supplies (AUS) is in North of England and supplies (amongst other products) industrial steel work for Electrical, Rail, and Telecom sectors since 1998. It employs 54 staff with an annual turnover of '9 million.

A programme of digitisation was implemented and one of the issues initially identified as a pilot was to address the "offcut issue". During production excess raw material of varying lengths are left over and historically these are stored and are used in an ad hoc manner involving manual inspection and measurement of the offcuts before orders are placed with suppliers. This was an issue that management had been aware for some time but had been unable to successfully resolve.

Utilising Lean improvement techniques this process was mapped out and improvements suggested following 5S and 7 Wastes thinking, in addition as much of the process as possible was digitised and incorporated into the update of the organisation's ERP system.

This novel approach has resulted in a 40% increase in the productivity of the process and greater stock visibility. More importantly for the organisation, it has provided a successful case study of the application of a Rapid Improvement Cycle and upskilling of key operational staff in Lean improvement techniques, which has paved the way for further digitisation of the production planning.

3 - Hexaly Studio: no-code modeler for routing and scheduling problems

Lucas Ligny

Hexaly Studio is a no-code SaaS platform for mathematical optimization. Hexaly No-Code Modeler allows users to create a mathematical optimization model based on a business description of its characteristics. The verticals currently handled by Hexaly No-Code Modeler are Vehicle Routing and Production Scheduling. Consequently, using Hexaly Studio, software developers and data scientists can build rich Vehicle Routing or Production Scheduling apps without writing a line of code. This no-code approach is particularly powerful for fast prototyping.

For each vertical, the user can describe the business problem - decisions, constraints, objectives - by selecting the appropriate business features along a straightforward workflow. Then, the Hexaly No-Code Modeler builds a Hexaly model, together with sample data inputs and a dashboard with appropriate widgets to visualize the solutions provided by Hexaly Optimizer. The widgets can be texts, tables, maps, (Gantt) charts, etc. Having explored the solution using sample data, the user can feed the Hexaly model with real-world data and adjust the model constraints and objectives in no-code, or directly by customizing the Hexaly model.

Decarbonized energy systems & markets

Stream: Energy Markets

Invited session

Chair: Thomas Klatzer

1 - Fully Flexible Temporal Resolution for Energy System Optimization

Zhi Gao, Germán Morales-Espana, Diego Tejada, Matteo Gazzani

To facilitate the transition towards climate-neutral energy systems, many decision-makers rely on Energy System Optimization Models (ESOMs). However, the complexity associated with operational decisions in the numerous time steps can bring a tremendous computational burden. So far, most efforts have been dedicated to creating typical periods to represent the full horizon, with repetitions in a uniform resolution. On the other hand, owing to the various natures of operational decisions, a uniform resolution might not be necessary. In fact, it has been proposed to designate separate resolutions for certain sections of the system. In that method, temporal period lengths have to be multiples of each other. Taking this to a new level, we propose a concept and mathematical formulation of fully flexible temporal resolutions, where energy flows and balances can have independent and dynamically varying resolutions. Furthermore, we present a case study of the optimal operation of the Northwest EU power system to demonstrate its advantages, utilizing TulipaEnergyModel.jl, an open-source ESOM tool. Results show that compared to using traditional uniform resolution, a simplification enabled by the fully flexible resolutions gives a relatively more accurate solution while incurring less computational cost. The time spent formulating the optimization problem also drops proportionally.

2 - Bet on horses, not unicorns - The impact of technology optimism on the decarbonization of the European energy system

Jacob Mannhardt, Giovanni Sansavini

The European and global energy systems need a drastic shift toward low-carbon technologies to achieve deep decarbonization across all sectors. Technological innovation is crucial for facilitating an economically and ecologically viable transition. However, a widespread concern exists that overly optimistic anticipation of emerging low-carbon technologies, i.e., "unicorn technologies", may delay effective emission reductions today. In this study, we quantify the impact of technology optimism emerging from various forecasting errors, e.g., infinitely fast capacity expansion, on the feasibility and cost of the European energy transition. To this end, we describe the decision-making process as a myopic planner who plans their investment and operation based on a foresight horizon with an overly optimistic technology forecast. Using the linear cost-minimization framework ZEN-garden, we optimize the transition of the sector-coupled European energy system, including the electricity, residential heating, transport, and industry sectors. We investigate the dependency of the energy transition on such "unicorn technologies" and quantify the change in the investment strategy when the decision-maker plans with erroneous forecasts. We find that the overly optimistic forecast leads to a delayed investment in mature low-carbon technologies and, therefore, increased emissions in early years because the decision-maker wrongfully assumes to be able to remove or abate them in the future.

3 - A Tight Approach on Piecewise Linear Pipeline Gas Flow Modeling with Linepack

Thomas Klatzer, Germán Morales-Espana, Diego Tejada, Sonja Wogrin

Integrated power and gas energy system optimization models (ESOMs) can be a valuable tool for planning decarbonized energy systems. In this context, pipeline gas transmission is a particularly complex problem due to the nonlinear and nonconvex relation of (bidirectional) gas flows and gas pressure and the pipeline's capacity to be used for short-term gas storage (linepack). One method to deal with this complexity is piecewise linearization, which implies formulating the ESOM as mixed-integer linear program (MILP). In the literature, several general piecewise linearization methods with the desirable characteristics of tight formulations have been applied. However, these methods are not tailored to this specific problem and thus tightness is harmed. Against this background, we propose a novel piecewise linearization method for the pipeline gas transmission problem with linepack. By computing the tightest possible polyhedra equivalent to its linear systems of constraints, we show that the proposed formulation is tight per se while others are not. The resulting computational advantages are demonstrated in a case study of an integrated 24-bus power and 12-node gas system interlinked by gas-fired generators (based on discrete unit commitment decisions).

4 - Modelling competitive pumped hydropower

Erik Bjørnerem

Balancing increasing shares of variable renewable generation requires flexible technologies such as hydropower. However, hydropower representation is often oversimplified in current power system investment models, leading to an overestimation of the flexibility potential. More accurate representations are therefore required to correctly map the available resources. A common simplification is reservoir aggregation, which removes complexity added by reservoir couplings. This information becomes increasingly important for pumped hydropower operation, to account for individual reservoir capacity limits and flow constraints between reservoirs. Additionally, deterministic formulations do not account for any uncertainty or variation in inflow or the availability of wind and solar resources. This is crucial to include for systems with a high share of generation from variable renewable sources.

This work aims to combine techniques from power system investment models with hydropower operational models to more accurately represent the flexibility from pumped hydropower storage. This framework

is then to be used to compare the viability of large-scale pumped hydro-power storage in Europe to other storage solutions, such as battery or hydrogen storage, under different policy scenarios for carbon emissions.

1 - Patient reallocation for waiting time reduction in emergency departments within multi-hospital networks

Dario Nicola Marchese, Sebastian Birolini, Mattia Cattaneo

The timely provision of emergency care has emerged as a significant challenge due to a consistent rise in the number of visits to emergency departments each year. However, there has been no corresponding expansion in hospital resources and infrastructure, resulting in a high level of overcrowding. One of the primary reasons can be attributed to non-urgent patient visits, which account for 80% of the total accesses. This work focuses on the patient reallocation strategy, illustrating how transferring non-urgent patients between EDs within the same multi-hospital network can effectively decrease waiting times. To implement this approach, we devise a novel multi-objective optimization model with an intrinsic two-stage structure, where arriving patients can be either admitted or diverted to another hospital according to system capacity and congestion, and subject to consistent vehicle routing and availability. The proposed model is applied to a real-case study involving a multi-hospital system in northern Italy, attaining an average reduction of over 35% in daily waiting times. Extensive numerical experiments are conducted to demonstrate the scalability of the model and quantify its benefits in various settings. Based on the experimental outcomes, we develop a machine learning algorithm which serves as a tool to quickly assess the potential of the reallocation in a given hospital network with minimal information and provides insights on the required fleet size.

2 - Optimizing Patient Flow and Personnel Welfare in Emergency Departments: A Multi-objective Approach

Burak Pac

Emergency room overcrowding remains a significant challenge in healthcare systems worldwide, often involving several-hour-long waiting times for patients and creating a stressful, intense environment for physicians and nurses. Traditional strategies, such as redirecting arriving ambulances to alternative emergency departments, have limitations in fully optimizing patient flow and resource allocation. This study presents a novel approach to address this issue by systematically redirecting patient demand to specific emergency departments, integrating real data analysis with system modeling. The primary objectives include minimizing system time for patients, ensuring equitable emergency room crowding levels, and maximizing emergency physician and nurse welfare by accommodating their preferences regarding location and shift schedules across a network of public emergency medical centers within the city. By considering factors such as travel times, patient volume, and service durations, the proposed methodology aims to optimize system performance using multi-objective computing budget allocation for non-dominated sorting particle swarm optimization. Additionally, the study explores the use of genetic programming as an alternative approach. This research offers a comprehensive solution to the complexities of patient flow management in emergency departments, with promising implications for practical implementation in healthcare systems.

3 - Capacity Balancing Algorithm for Placement of Observation Patients: Assessing the Effect on ED Crowding

Vera Tilson, Dessi Pachamano, Shiya Xiao, Keely Dwyer_Matzky

We examine the queuing performance of a real-time capacity-balancing (CB) algorithm for routing patients from the Emergency Department (ED) to an Observation Unit (OU) or to an inpatient ward. We study the significance of relative bed capacities between the ward and the OU. OUs are designed for specific patient types, with shorter expected hospital stays. By redirecting patients and reserving OU capacity for those who benefit most, overall hospital stay durations are reduced. However, high ward utilization may cause longer ED waiting times. To prevent ED crowding, implementing a CB algorithm requires careful analysis of ward and OU long-run utilization.

4 - Dependence between patient arrivals and service times in emergency department data

Laura Boyle

Hospital emergency departments are frequently modelled components of healthcare systems, owing to their importance in primary healthcare access and to their scrutiny in politics and the media. Queueing models are routinely used to model emergency departments and it is commonly assumed that service time distributions are independent of system state. This talk will explore a motivating emergency department dataset to discuss the dependence between patient arrivals and service times. A method for detecting the source of the dependence will be presented and the implications for developing accurate queuing models of hospital systems will be discussed.

Wednesday, 8:30-10:00 - Room: 12 (building: 116)

Scenarios and foresight practices: Behavioural issues I

Stream: Behavioural OR

Invited session

Chair: *Martin Kunc*

1 - Behavioural aspects of system dynamics use with scenarios

Martin Kunc

System dynamics (SD) is a methodology to generate qualitative and quantitative models. SD has two main concepts that are highly suitable to use with scenarios: feedback processes that define the structure of sociotechnical systems and accumulation processes that are responsible for the dynamic behaviour of systems over time. Kunc (2023) proposes framework that integrates methodologically scenarios and SD where the integration can take multiple forms depending on the use of SD for creating or supporting scenarios. Lane (2017) proposes a behavioural focus for SD in terms of its contributions related to mental models, encountering the world, building and implementing formal models, and content of formal models. This work evaluates how the behavioural focus of SD can support overcome some of the behavioural issues in scenario development process such as cognitive biases, effective group facilitation and overcoming business-as-usual thinking (Bryson et al, 2016)

2 - Accuracy, Awareness, and Acceptance: How Attention Drives People's Use of Point versus Interval Forecasting Algorithms

Bas van Oudenhoven, Rob Basten

Many operations rely on forecasts of future events, often determining the allocation of significant sums of money. Fortunately, algorithmic forecasts achieve high levels of accuracy, but many decision-makers reject algorithms upon observing they are not perfectly accurate. What determines whether decision-makers perceive an algorithm as inaccurate, and how are these perceptions related to their willingness to use

algorithms when forecasting future events? We propose that the tendency to dismiss algorithmic advice is partially due to the common practice of presenting forecasts as single points rather than intervals. In Study 1, we find that people perceive equally imperfect forecasts as more accurate when these forecasts are presented as intervals rather than points. In Study 2, we examine how these differential accuracy perceptions affect people's willingness to use algorithms. Here, we find that people do not necessarily favor interval over point forecasts when deciding whether to rely on the algorithm's forecasts. Instead, such preference only occurs when people are explicitly prompted to evaluate the algorithm's accuracy before deciding whether to commit to its forecasts. In sum, these findings underscore the complex processes underlying people's perceptions of algorithmic errors and their subsequent reliance on algorithms. Moreover, they show how managers can apply interval forecasts to effectively increase human forecasters' reliance on forecasting algorithms.

3 - Causal Machine Learning: A Methodological Shift in Explainable AI for Decision Making

Rosa Taghikhah

Explainable AI (XAI) aims to enhance the transparency and interpretability of AI systems, a crucial need in decision analytics where understanding AI decision-making processes can significantly influence trust and operational adoption. Traditional XAI models often focus on one-to-one mappings between inputs and outputs, providing localized explanations for individual predictions. This approach, while useful, falls short in capturing the complex, interconnected relationships inherent in many real-world data sets. It particularly struggles with dynamic environments where feedback loops and interactions among variables play critical roles in shaping outcomes. These limitations highlight the need for more sophisticated methods that can unravel the intricate web of relationships and their causal effects on predictions. Causal machine learning offers a promising avenue for advancing explainability by focusing on the identification and understanding of causal relationships rather than mere correlations. Unlike traditional XAI models, causal approaches seek to model the entire system of variables and their interactions, including feedback loops. This enables a more comprehensive view of how changes in one part of the system can ripple through and affect other parts, providing insights into the mechanisms driving predictions. This enables insights into the mechanisms driving predictions.

4 - Scenario Simulation and Forecasting of Circular Chemical Economy: Assessing Policy Impacts on Investor and Consumer Behaviour for Policy Decision-Making

R. M. Kazakov, Bing Xu

This paper proposes the development of a decision support tool aimed at evaluating the impacts of regulatory measures within the circular chemical economy framework. Building upon previous research in the field and addressing identified barriers and challenges, a system dynamics simulation tool is being developed. This tool will enable stakeholders to assess the effects of regulatory interventions on investor and consumer behaviours, aiding policy decision-making processes. By employing simulation scenarios that consider different regulatory frameworks, the tool facilitates the evaluation of potential shifts in investment patterns and consumer preferences, offering insights crucial for policy formulation and implementation. The transition towards a circular chemical economy necessitates proactive policy measures to promote sustainable practices and mitigate environmental impacts. However, understanding the multifaceted impacts of regulatory interventions on investor and consumer behavior remains crucial for effective policy decision-making.

1 - Upgrading arcs in the covering tour problem

Marta Baldomero-Naranjo, Andrea Mancuso, Adriano Masone, Antonio Manuel Rodriguez-Chia, Claudio Sterle

In this study, we present the Covering Tour Problem with Arcs Upgrade (CTPAU). This problem is an extension of the Covering Tour Problem (CTP) that considers the possibility of enhancing the network by reducing the length of some arcs, i.e., upgrading them. Hence, upgrading an arc means reducing its length, usually within certain limits, at a given cost that is proportional to the extent of the upgrade.

The CTPAU is formulated with three different sets of nodes, V , W , and T that is a subset of V . Two decisions have to be made simultaneously: i) identify the tour of minimum length that passes through a subset of V , ensuring that all nodes of set T are included in the tour, and that each node in W is within a given coverage distance from a node on the tour, ii) decide with connections to upgrade.

Therefore, the CTPAU seeks to identify the minimum length tour while integrating arc upgrading and a budget constraint. In this context, we present some MILP formulation and compare them to illustrate the potential and limitations of each one.

2 - Building Resilience of Critical Infrastructures in Times of Crisis

Emilia Grass

In times of crisis, healthcare systems and aid agencies face unprecedented challenges, necessitating robust resilience strategies to ensure uninterrupted service delivery. This talk emphasizes the importance of preparedness, adaptability, and the strategic use of Operations Research (OR) techniques within these critical sectors. For healthcare, building infrastructure resilience involves enhancing cyber security, securing supply chains, and integrating advanced decision support tools to maintain care continuity. OR techniques play a crucial role in optimizing resource allocation, forecasting demand, and planning emergency responses. Similarly, disaster management and aid agencies must focus on agile response strategies, leveraging OR for data analytics and informed decision-making, and fostering partnerships across sectors to mobilize resources swiftly. Central to these efforts is a holistic approach that combines physical infrastructure enhancements with systemic resilience through OR, ensuring services can withstand, adapt to, and recover from disruptions. By prioritizing resilience and applying OR methodologies, healthcare and aid organizations can safeguard vulnerable populations during crises, contributing to societal stability and well-being.

3 - A methodology to tackle multi-objective linear programming problem

Mariana Mesquita-Cunha

Multi-objective decision-making often poses challenges due to the computational complexity of generating and analyzing the Pareto front. To address this, we propose a framework integrating two strategies to alleviate the burden on decision-makers (DMs). Firstly, we introduce algorithms based on the epsilon-constraint method to derive a Pareto front representation balancing coverage, uniformity, and cardinality, thereby reducing the number of non-dominated vectors to be considered. Secondly, we incorporate DM preferences to refine the feasible region. We do so initially using criteria ranking and selecting a region of interest of the Pareto front to focus the representation. Then, after generating the initial representation, through pairwise comparisons we construct convex cones and eliminate inferior regions from consideration. We demonstrate the efficacy of our framework through its application to pharmaceutical supply chain design, illustrating its

adaptability aid in tactical and strategic decision-making contexts. This methodology offers a practical approach to multi-objective optimization challenges, providing DMs with manageable decision support while maintaining focus on the proposed strategies

4 - An overview of Arc Routing Problems with drones

Paula Segura Martínez

In the last decade, the emerging technology of unmanned aerial vehicles, commonly known as drones, has provided new opportunities for practitioners in urban logistics. Drones present attractive advantages compared with standard ground vehicles, such as avoiding the congestion on road networks, eliminating the risk of personnel in difficult access operations or getting higher measurement accuracy in infrastructure inspection. The use of drones to perform the service in Arc Routing Problems (ARPs) involves significant changes in the traditional way of modeling and solving them. While in traditional ARPs the ground vehicles are limited to travel through the edges of a network (following the local infrastructure), drones have the flexibility to travel off the network as well. These aerial vehicles may service only part of an edge and then travel in a straight line to any point of another edge, without following the links of the network. This consideration makes Drone ARPs continuous optimization problems with an infinite and uncountable number of feasible solutions. In this talk, I summarize these ideas and review some variants of ARPs with drones that we have addressed and studied during my doctoral thesis.

Food Supply Chains

Stream: Secure & Sustainable Food Supply
Invited session

Chair: *J.c. Gerdessen*

1 - Food network design with quality deterioration considerations: an application to a perishable food supply chain

Junhan Zhang, Peter Kirst, Sander De Leeuw, G.D.H. (Frits) Claassen

Given the increasing demand for freshness, the need to reduce food waste, and to ensure food safety, it is crucial to consider quality deterioration processes in the (re)design of food supply chains. Past developments in food supply chains focussed foremost on efficiency and economic profitability, resulting in large-scale, centralized processing facilities. This has become a liability as efficiency in large-scale processing limits product differentiation and flexibility. Decentralised, (upstream) pre-processing, and improved pre-treatments can affect product deterioration in an early stage and will result in more diverse and intermediate product flows that can be used in existing and new value chains and provide new markets. To identify the benefits of alternative supply chain structures, we propose a generic model based on mixed-integer linear programming. The modelling structures are applicable to a broad variety of different (food) supply chains. Both network design aspects and gradual quality deterioration processes are incorporated. We illustrate the applicability of the concept from an existing fruit supply chain in China. The results show that decentralized pre-processing can mitigate quality deterioration processes. In addition, a decentralised supply chain leads to improved sustainability from a social point of view since smallholder farmers in emerging economies can increase their income without affecting the profits of downstream stakeholders.

2 - OR based solution for distribution of grains within a state

Shallu Bhasin, Nomesh Bolia

The Public Distribution system (PDS) distributes essential food and non-food items to the economically disadvantaged population. The distribution is often facilitated through a network of state warehouses and fair price shops. Each year, the Government of India spends a huge amount of money on the distribution of these grains across the nation, from surplus to deficient regions, which puts a heavy burden on financial resources. The present study aims to optimise the PDS operations to improve logistical decision-making and thereby reduce the cost to the government. The mathematical model is developed using mixed integer linear programming, which cost. The constraints considered in the model are demand constraints, supply constraints, and capacity constraints. The parameters includes capacity, demand, geo-coordinates, and district name. The outputs are optimal tagging and associated amounts of food commodities to be transported and optimal clusters for storage facilities significant. The above model has been implemented for 3 months in one of the states where the state has reported a reduction in the cost to the government. Efforts are underway to scale the exercise to all other states.

3 - Facilitating System Dynamics to Analyze Digital Logistics Platforms for Regional Food Supply

Christine Mendoza Pardo, Christian Fikar

In our work, we use system dynamics to investigate the influence of digital solutions aiming to enhance the regional food supply for the hospitality industry and communal catering. A systems thinking approach is applied to identify feedback structures and underlying interdependencies. Therefore, findings from literature and two model regions were collected. With the help of causal loop diagrams, the results get visualized. They indicate that digital solutions can help to overcome key obstacles in such systems, namely insufficient logistics solutions as well as a lack of communication and transparency.

4 - Decentralized and circular plant-based protein supply chain networks for the future [U+202F] [U+202F]

Ege Naz Ozer, Sander De Leeuw, G.D.H. (Frits) Claassen

Global protein consumption is shifting towards plant protein sources due to population increase, resource depletion, requirements for diversifying diets, and the need to reduce environmental impact. This study aims to redesign the European Union (EU) plant protein processing supply chains for the current and the future state of the plant-protein food market. [U+202F] In this study, this network design problem is formulated as a multi-objective mixed integer linear programming (MILP) model, incorporating decentralized processing operations and the re-use of waste streams across various echelons for side stream valorizations and to form closed loops. The Pareto front is obtained for the minimization of environmental impact and maximization of economic gain. Numerical experiments for technology development and replacement of animal protein with plant protein production and consumption demonstrate that the current supply chain framework can be extended to cover the shift towards plant protein sources, but the network structure depends on the processing technology capabilities and available pathways of value recovery.

Wednesday, 8:30-10:00 - Room: 18 (building: 116)

Home Health Care and Operating Room Scheduling

Stream: OR in Health Services (ORAHS)
Invited session

Chair: *Kris Braekers*

1 - Quantifying the trade-off between costs and nurse satisfaction in home healthcare planning decisions

Arne Delaet, Kris Braekers, Katrien Ramaekers, Patrick Hirsch

Home healthcare (HHC) nurses in the Flemish context face a significant challenge: the irregularity of work rosters in successive rostering periods, which disrupts their ability to plan personal activities. This issue affects their job satisfaction and contributes to high turnover rates within the industry.

Existing literature predominantly addresses nurse satisfaction in HHC through single-objective models using a weighted sum, often failing to capture the complex trade-offs involved. In addition, decision-makers struggle to assign appropriate weights to each factor in this function.

This study proposes a bi-objective model to balance costs and care worker satisfaction, defined by roster regularity in successive planning periods. Our novel approach utilizes a multi-directional local search (MDLS) framework with an embedded matheuristic to approximate the Pareto frontier between the conflicting objectives (i.e., costs and care worker satisfaction). This matheuristic constructs multi-day planning in an integrated manner by rostering nurses, assigning patients to nurses, scheduling patient visits and constructing routes. Our model offers decision-makers valuable insights for optimizing rostering practices by presenting multiple solutions that highlight trade-offs. Finally, the effectiveness and performance of our solution approach will be demonstrated by discussing the results of some empirical experiments.

2 - Home healthcare routing and scheduling with task-splitting

Loek van Montfort, Markus Leitner, Wout Dullaert

This study introduces the concept of task-splitting into home healthcare routing and scheduling, focussing on the design of routes and time-tables for caregivers providing services at patients' homes. Task-splitting entails the division of a (long) patient visit into two separate visits, which can be performed by different caregivers at different times. Splitting a visit can increase the planning flexibility of home healthcare (HHC) providers, as the resulting split tasks may have lower requirements related to the caregiver qualifications, relaxed visiting time-windows, or a shorter combined duration. However, the inclusion of task-splitting together with the temporal dependencies that arise between the split parts also presents a computational challenge. To support the incorporation of task-split decisions into the planning process and explore the impact for HHC providers, we first introduce different mixed integer linear programming formulations. Next to deciding which tasks to split, these formulations are capable of handling various types of synchronisation constraints between the visits. Subsequently, we propose pre-processing routines and heuristic procedures to improve the computational performance of the resulting solution algorithm. Finally, we present results from a computational study that demonstrates the potential benefits of task-splitting, including a reduction on the staff requirements and decrease of operations costs among the instances considered.

3 - Collaborative Scheduling and Routing of Home Healthcare Service across Multiple Communities

Wenjie Hu, Yang Wang, Jin-Kao Hao, Jianguang Feng

As an important home health care mode in China, the home-community service mode focuses on the impact of healthcare centers in each community and coordinates the medical resources between communities. In this paper, we propose a new collaborative home health care routing and scheduling problem in multiple service centers (C-HHCRSP). In addition to the traditional routing and scheduling decisions, C-HHCRSP also assigns a working center for each highly qualified caregiver who can provide health services across multiple communities. This problem is challenging due to the presence of complex, realistic constraints such as mandatory lunch breaks, synchronized visits, and downgrading of services. We first formulate the problem as a mixed integer programming model, which is solved by CPLEX. Then, we propose an adaptive large neighborhood search (ALNS) algorithm that integrates new problem-specific destroy and repair operators. To further improve the performance of ALNS, we propose two post-optimization techniques, which are based on heuristic strategies and a set partitioning model, respectively, resulting in the enhanced algorithms ALNS-HS and ALNS-SP. Tested on 104 benchmark instances, ALNS-HS shows a competitive performance with CPLEX on small instances. For large instances, we compare our algorithms with

a classic large neighborhood search algorithm to demonstrate their superiority. Additional analyses are performed to verify the roles of the components of our algorithms.

4 - A two-layer heuristic for patient sequencing in the operating room theatre considering multiple resource phases

Babak Akbarzadeh, Broos Maenhout

In this paper, we study the surgery scheduling problem in the operating room theatre. The problem considers the sequencing of patients and calculation of their start times with splitting of surgeries into resource phases to facilitate the efficient use of different types of resources. We propose a dedicated two-layer heuristic to compose an operational patient and resource schedule. The first optimisation layer applies an evolutionary heuristic to devise patient schedules while considering the scheduling of the operating surgeons and rooms. This step employs a machine-learning mechanism predicting the feasibility of chromosomes, which improves the algorithm's efficiency and effectiveness, and relies on novel local search operators to find high-quality solutions. The second layer devises the schedule of the other resources using a decomposition-based heuristic. Computational experiments are conducted to show the performance of the proposed two-layer heuristic and validate its design choices. We benchmark the proposed algorithm with other optimisation procedures and show the contribution of considering multiple resource phases for real-life decision-making.

Fairness in sports

Stream: OR in Sports

Invited session

Chair: [Laszlo Csato](#)

1 - Analysis of Perception Differences in Football Video Refereeing

Cristian Dobre

The Video Assistant Referee (VAR) is introduced in football to guarantee consistency and accuracy in the appliance of the official playing rules. The VAR must avoid appraisals that are prone to interpretability, and must ensure fair play. However, as with every subjective judgment procedure, differences in perception might arise. This work has gathered statistical evidence that even with use of the VAR, conclusions on the same game situations will still differ among more referees judging it behind the VAR screens. This was achieved by studying the performance of the Dutch football referees who are asked to judge game situations based on video replays. For all game situations, the referees are requested to classify the violation of the fouls rules into 11 ordered categories (from 0 = no violation of the rules up to 10 = strict violation of the rules resulting in a red card). The discrete scores given by the referees are transformed into continuous scores, as required by the Analysis of Variance models, using linear optimization techniques. The statistical methods show enough evidence that there is difference in perception between several referees. Subsequently, groups are formed such that each group contains referees that have similar perception for more uniformity in decision making.

2 - How to organize a fair rogaining competition?

David Van Bulck, Joonas Pääkkönen, Benjamin Jacquet, Dries Goossens

Orienteering is a cross-country running sport where competitors use a map and compass to visit control points as quickly as possible. In a special variant called rogaining, each control point is assigned with a score, competitors are allowed to visit the given controls in the order of their own preference, and there is a time limit that prevents competitors from visiting all control points. Hence, it is important for the competitors to carefully plan which controls they are going to visit (like in the knapsack problem) and in which order (like in the traveling salesman

problem). Thus, winning a rogaining competition not only requires physical but also planning and navigational skills.

Unlike most operations research literature, we approach the rogaining problem from an organizers' perspective: how to assign scores fairly, balancing physical and strategic skills? In practice, this typically translates to designing rogaining competitions such that brute physical skills are not overly favored. We follow a bi-level optimization approach where the outer-layer assigns scores to control points and the inner-layer simulates a portfolio of pre-defined competitors. The result is a Pareto front of possible score assignments with distinct trade-offs between physical and strategic skills. Our method's efficacy is shown in its application to the 2023 rogaining world championships.

3 - The allocation of FIFA World Cup slots based on the ranking of confederations

Laszlo Csato

Qualifications for several world championships in sports are organized such that distinct sets of teams play in their own tournament for a predetermined number of slots. This paper provides a reasonable approach to allocate the slots based on historical matches between these sets of teams. We focus on the FIFA World Cup due to the existence of an official rating system and its recent expansion to 48 teams. Our proposal extends the methodology of the FIFA World Ranking to compare the strengths of five confederations. Various allocations are presented depending on the length of the sample, the set of teams considered, as well as the frequency of rating updates. The results show that more European and South American teams should play in the FIFA World Cup. The ranking of continents by the number of deserved slots is different from the ranking implied by FIFA policy. We recommend allocating at least some slots transparently, based on historical performances, similar to the access list of the UEFA Champions League.

Invited session

Chair: *Sadia Samar Ali*

Chair: *Elise del Rosario*

1 - Modelling of emergency medical services in Indonesia

Paul Harper, Sarie Brice, Mark Tuson, Geraint Palmer, Daniel Gartner

Our research programme is working with Indonesian emergency ambulance services and the Indonesian Government to help them make critical decisions on the optimal types, capacities and geographical locations of response vehicles. Such factors directly impact on the probability of patient survival, ability to respond to major disasters, and the overall quality of care provided. There are however many challenges faced in the country, including vast geographical areas, traffic congestion, inadequate numbers of ambulances and a lack of a co-ordinated service.

This talk will describe findings and impact of the research project to date, including an analysis of ED survey data that we undertook across Jakarta hospitals, and an approach to consider EMS allocations for both heterogeneous populations (multiple medical needs) using a heterogeneous fleet (consideration of multiple vehicle types each with differing travel speeds). This has been achieved via the creation of an optimisation and simulation decision-support framework.

2 - Cost-effectiveness of a menstrual hygiene program in rural India

Merin Mathew, Malavika Krishnakumar, Radhika Menon, Sreesankar Ajayan, Raghu Raman, Prema Nedungadi, Georg Gutjahr

Improving menstrual hygiene and reproductive health is one of the United Nations' Sustainable Development Goals. Intervention programs target girls in developing countries and provide them with knowledge and material to manage menstruation. This paper considers the cost-effectiveness of such programs with a case study from a rural area in Madhya Pradesh, India. A sequence of maximal-covering location problems (MCLPs) was solved to select a set of villages as optimal locations to conduct multiple interventions in the study area. Pre- and Post-surveys with participants are used to estimate the proportion of girls who adopted safe and hygienic menstrual practices. Interviews with 528 adolescent girls from nearby villages are employed in a diffusion model to estimate the indirect reach of the intervention across the neighboring villages. Health benefits are measured in terms of Disability-Adjusted Life Years (DALYs). The cost-effectiveness ratio of a menstruation intervention is estimated to be about \$28.5 per DALY. These programs also provide additional benefits such as an increase in awareness, a reduction in school absenteeism, and an increase in the self-confidence of girls.

3 - Prevalence and costs of delayed discharge in a tertiary Indian hospital

Georg Gutjahr, Merin Mathew, Malavika Krishnakumar, Rejitha P S, Preetha P, Binil Babu, Ajitha Aniyappan, Merlin Moni, Dipu T. S.

In India and other low and middle-income countries, delays in the approval of medical procedures from insurance companies often lead to extended hospital stays. Patients can not be discharged until the insurance company approves all procedures.

In this talk, we study the prevalence of the problem and the financial implications by analyzing all discharge summaries from 2021 to 2023 in a tertiary hospital in Kerala, South India. Unnecessary hospital stays will cause substantial economic loss to the hospitals. They will also lead to patient dissatisfaction and reduced bed availability for patients with medical needs.

If the hospital allocates additional resources, it can improve discharge planning through system-level approaches. In this talk, we investigate the implications of different hospital policies. We use counting processes to model patients' arrival on each day, survival models for the length of hospital stays, and a Markov decision process to model the effects of different policies. The decision variables can be optimized by approximate dynamic programming. We find that policies that prioritize a timely discharge should be recommended. Beyond costs, these policies also increase patients' satisfaction and the overall efficiency of the health care system.

1 - Towards an optimum carbon backbone: A Bilevel Model Approach for Efficient CO2 Pipeline Design and Price Policy in Germany

Vladimir Stadnichuk, Stephan Bogs, Ali Abdelshafy, Grit Walther

The pressing challenge of climate change and the need to reduce the levels of anthropogenic carbon dioxide emissions (CO₂) have made Carbon Capture and Storage (CCS) an increasingly critical area of research. CCS represents a vital technology in the pursuit of mitigating climate change impacts by capturing CO₂ emissions at their source and storing them underground. Recognizing the importance of this

technology, our study delves into the optimization of CCS infrastructure, specifically focusing on the integrated design of CO₂ pipeline networks and the development of effective price policies. Through a bilevel model tailored for the CCS context, we examine the potential of price policies to enhance the efficiency of CO₂ pipeline networks in Germany. Herein, our findings illuminate the dual nature of CCS: on one hand, it offers a pathway to lower CO₂ prices for emitters, thus promoting environmental welfare. On the other hand, it encounters challenges in market design, particularly in addressing the complex issue of preventing monopolistic control by pipeline operators. Additionally, we recognize the 'distance-to-sink' effect as a significant barrier, disadvantaging emitters situated far from storage sites.

2 - Green Skies Ahead: Streamlining the Sustainable Aviation Fuel Supply Chain in New Zealand

Hadi Vatankhah Ghadim, Ali Ebadif Torkayesh, Jannik Haas, Rebecca Peer, Grit Walther, Sandra Venghaus

Presently, the domestic aviation sector in New Zealand emits approximately 825 kilotons of CO₂ equivalents, positioning the country among the top 10 OECD nations with the highest per capita CO₂ emissions from domestic flights. Therefore, transitioning away from conventional fossil fuels to more sustainable alternatives, notably Sustainable Aviation Fuels (SAF), is inevitable. Enabling an effective transition to SAFs requires understanding the share of different SAFs to meet future demand, the timing and location of production plants, fuel transport between different regions and airports, the resource use for SAF production, and all associated economic investments. To address this gap, we present a mixed-integer linear programming model to support the development of SAFs in New Zealand. The proposed framework optimizes the SAF supply chain, considering different production processes, to provide an evidence base to support the transition towards SAF integration. In this first case study, we consider the domestic aviation industry and domestic SAF production using indigenous resources. Ultimately, integrating these fuels will lead to decarbonization in the aviation sector and contribute to the country's environmental and climate change goals.

3 - Sustainable power generation pathways: EMPIRE model insights for European countries

Shamim Homaei, Rahul Anantharaman, Stian Backe, Simon Roussanaly, Asgeir Tomasgard

As global efforts intensify to meet the targets of the Paris Agreement, the necessity to reduce emissions from the power sector becomes increasingly evident. This study explores the role of different power generation technologies in achieving emission reduction targets. For this purpose, the European Model for Power System Investments with Renewable Energy (EMPIRE) is used to optimize power generation pathways across Europe by 2050. The primary focus is on understanding the impact of CCS technology, exploring the balance between different generator types (renewables, biomass, nuclear, and fossil-based generators) and their collective contribution to decarbonizing the power sector. Notably, the study considers high capture rate CCS technology to reveal its potential to reshape the energy mix. The research also develops various pathways associated with CCS and without CCS technology, offering a comprehensive understanding of how these pathways contribute to the decarbonized power system. Moreover, the study illuminates the impact of these pathways on electricity prices and provides valuable insights into potential changes. Our findings emphasize the crucial role played by CCS in transitioning towards a green power sector and shaping sustainable power generation pathways. In addition to offering practical insights for policymakers, the study illustrates the dynamics of the power system transition and proposes a roadmap for a more sustainable and resilient energy future.

4 - A TEMA-Europe-based scenario analysis to examine crucial strategies for decarbonization

Daniele Lerede, Valeria Di Cosmo

Europe still has a strong dependence on fossil fuels, and natural gas in particular, despite the claimed commitments towards carbon neutrality by 2050. The REPowerEU Plan is reducing the huge amount of gas imported from Russia. Nonetheless, the main strategy to guarantee security of supply mainly envisages long-term agreements with

more reliable partners for gas and a larger support to the development of renewables. At the same time, a carbon-neutral energy generation technology nuclear fission is undergoing a substantial phase-out, and the use of fossil fuels for energy production is discouraged through the adoption of growing carbon tax levels in the form of excise duties and the Emissions Trading System. This work presents a scenario analysis carried out using the open-software and open-framework energy system optimization model TEMA-Europe. Taken for granted the absence of Russian gas imports starting from 2027, the examined alternative scenarios envisage: 1) a business-as-usual scenario; 2) a scenario with increasing carbon prices and constraints on nuclear capacity to simulate the current phase-out trend; 3) a scenario with increasing carbon prices and the possibility to increasingly rely on nuclear electricity; 4) a net-zero emissions by 2050 scenario. Energy costs, the profitability of renewable energy projects and the role of gas are evaluated for each of the mentioned scenarios providing useful insights for the development of the European energy system.

Wednesday, 8:30-10:00 - Room: 49 (building: 116)

Post-Disaster Relief Distribution

Stream: OR in Humanitarian Operations (HOPE)

Invited session

Chair: Lars Päsler

1 - Scheduling of Unmanned Aerial Vehicles for Disaster Response

Arya Misiç, Mert Kara, Selin Özpeynirci

Unmanned aerial vehicles (UAV) are becoming an increasingly prominent alternative to traditional methods in disaster response, providing rapid aid to regions where transportation becomes difficult after natural disasters. Optimizing the use of UAVs becomes even more important, especially considering the crucial role of rapid response and limited resources. This study focuses on developing efficient scheduling algorithms for UAVs that will be used in the distribution of emergency aid packages after natural disasters.

The goal of this study is to minimize the total weighted arrival time of aid packages to be distributed to the disaster area from multiple warehouses with UAVs. Given that UAVs can carry only a single package at a time, this problem becomes a scheduling problem. Within the scope of this study, the methods to be developed for the scheduling of UAVs to deliver aid packages to the disaster area will be tested on real-life scenarios designed for a potential earthquake in Istanbul, a region known for its high seismic risk.

By developing a mixed integer linear programming model, it is aimed to reach the optimal solution for small data sets. A heuristic approach is developed in order to find near-optimal solutions in reasonable time for large-sized instances of these problems, which are known to be NP-hard. The solution methods are applied on the Istanbul example, and insights are provided for disaster management planning.

2 - Post-disaster Relief Distribution Optimization Framework in Salgar, Colombia

Juana Jaramillo-Rios, Paula Penagos, Carlos A. Gonzalez-Calderon

Humanitarian logistics is crucial in crisis and disaster scenarios, enhancing system resilience and facilitating rapid restoration. Post-disaster relief distribution is a critical challenge, requiring efficient and effective relief to minimize suffering. The complexity of relief distribution involves navigating damaged infrastructure, coordinating with stakeholders, and adapting to dynamic conditions. The social impact of relief distribution, especially on vulnerable populations, is paramount. Ensuring accessibility to essential resources and efficient connectivity can mitigate suffering. Colombia, a developing country, is most vulnerable to natural disasters, climate-related risks, and economic instability. The 2015 flash flood in Salgar, Antioquia, caused 93 deaths and affected over 1,263 people. The community faces challenges in

post-disaster relief distribution, including damage assessment, accessibility, resource allocation, and efficient node placement. This research proposes an optimization framework for transportation networks to improve relief distribution efficiency and effectiveness in disaster-affected areas, leveraging a mathematical model. The framework uses multidisciplinary methods, including qualitative data analysis from humanitarian logistics experts and optimization algorithms for quick decision-making. It optimizes aid distribution to maximize coverage, minimize response times, and allocate resources.

3 - Hybrid simulation-optimization approach for planning relief-aid distribution

Mohanad Rezeq, Tarik Aouam, Frederik Gailly

During times of armed conflict, a number of security check-points are set up by authorities to regulate the movement of commercial and relief trucks into and out of the war region. These security check-points have become highly utilized, because of complex security procedures and increased truck traffic, which heavily slows down the delivery of relief aid. Our research aims to improve the process at the security check-points by redesigning the current process to reduce processing times and relieve congestion at check-point entrance gates. These efforts are then integrated with the proposed decision-support tool (the Clearing Function Distribution Model, CFDM) to minimize the effects of security check-point congestion on the entire humanitarian supply network using a hybrid simulation-optimization approach. Employing business process simulation, the current and re-engineered processes are both simulated, and the simulation output is used to estimate the clearing function (capacity as a function of the workload). Our efforts will contribute to improving the planning of the humanitarian network experiencing congestion at security check-points by minimizing the impact of congestion on the delivery lead time of relief aid to the final destination. For this, the Kerem Abu Salem security check-point in the south of GAZA is used as a case study. The results show that the CFDM tool works better when the Re-engineered-Clearing function's output is applied.

4 - Fleet Composition and Scheduling for Provision of En-Route Relief Aid Using an Adaptive Large Neighborhood Search with Decisions on the Intensive Margin

Lars Päsler, Merel Groen, Lisanne van Rijn

Refugees need periodic relief aid along their routes to safe places. To this end, continuation of service is crucial to alleviate their mental and physical burden. It has been shown that employing mobile facilities over fixed facilities to provide relief aid can reduce costs. The challenge in coordinating the number and schedules of mobile facilities has been formulated in the multi-period mobile facility location problem with mobile demand (MM-FLP-MD). Our research aims to determine the impact of using a fleet of different facility types and introducing capacity and duration constraints for facilities. We compare solutions from a Mixed Integer Linear Programming model and an Adaptive Large Neighborhood Search (ALNS). A prior proposed ALNS is enriched with additional operators and we exploit the problem's structure to permit a two-step repair procedure. Moreover, we discuss the application of an ALNS for decisions on the intensive margin, i.e. to make decisions from a non-binary decision space. This methodology is applied in a case study of the Western Balkan route during the 2015 European refugee crisis. We find that some of our operators provide similar improvements at a lower computational cost compared to the best operators in previous literature and some decision variables lie indeed on the intensive margin. An insight for humanitarian organizations is to use more smaller facilities in optimistic cost scenarios and favor larger facilities in more pessimistic scenarios.

Renewable Energy Challenges

Stream: Energy Management

Invited session

Chair: [Giovanni Masala](#)

1 - Sustainable Energy Transitions: Addressing Variable Renewable Energy Challenges with the AD-MERGE Integrated Assessment Model

Kamyar Amirmoeini, Olivier Bahn, Kelly de Bruin, Hamed Kouchaki-Penchah, Pierre-Olivier Pineau

In response to rising climate change challenges, the evolution of Integrated Assessment Models (IAMs) has been essential for a sustainable future. IAMs integrate environmental, technological, and socio-economic insights, to provide insight to sustainable planning. The recent significant cost reductions in Variable Renewable Energy (VRE) technologies have enhanced their adoption. However, VREs introduce complexities in modeling concerning system flexibility and grid stability. This study aims to assess the interplay between technological advances, grid integration, and market dynamics of VREs—elements fundamental to the decarbonization of the power sector. To achieve this aim, we incorporate a wider spectrum of power generation technologies into the AD-MERGE IAM, including updated options for hydro, fossil fuels, and nuclear, with a special focus on refining the integration and dynamics of VREs. Additionally, more energy storage solutions are introduced to enhance the model's technological representation. The improved storage options can enable the mitigation of the variability of VREs, ensuring a more reliable and stable energy supply. By evaluating the impacts of these advancements within the Shared Socioeconomic Pathway 2 scenario, our research addresses VRE integration challenges, seeks to overcome intermittency, and supports decarbonization targets.

2 - Data analytics for the impact of renewable energy impact on decoupling economic growth from carbon emissions

Ting Wu, Tao Wen, Yuwang Chen

Renewable energy contributes to reducing carbon emissions and attaining the general goal of energy sustainability, security and affordability in a balanced way. However, there exist complex causal relationships between renewable energy development, carbon emissions and economic growth, which makes it extremely difficult to reach consensus on key actions to address climate change across the globe. For example, in recent Climate Change Conferences, one of the key decision problems was how to mobilize climate finance and investment to renewable energy from developed countries in support of climate actions in developing countries. This work aims to develop data analytics to support the impact evaluation and strategy development of renewable energy, which helps to strike an informed balance between carbon reduction and economic growth in both developed and developing countries. The causal relationships between traditional and renewable energy consumptions, carbon emissions and economic growth in the world's major economies and carbon emitters are analysed both analytically and visually. The analytical results can be used to support data-driven decision making on net-zero strategies.

3 - Advancing Sustainable Mining: Integrating Renewable Energy through Optimization and Simulation

Boda Li, Chen Song, Ahmed Hajji, Diana Marcela Valencia Lucero

The mining industry, recognized for its high energy consumption and carbon emissions, faces pressing demands from customers for more sustainable practices. This work outlines a comprehensive approach to integrating renewable energies, into the mining sector to address these challenges. While the potential benefits of such integration include reduced energy consumption and emissions, it also presents significant

operational complexities. Mining equipment operates under intricate dynamics, and the fluctuating nature of renewable energy can complicate these operations further. Moreover, the mining industry's need for a continuous power supply necessitates that renewable energy integration is reliable and capable of meeting energy demands. To tackle these challenges, we propose the construction of optimization problem tailored to the complex operational dynamics of mining equipment and corresponding process, aimed at minimizing energy consumption while maximizing the use of renewable energy. Given the uncertainties inherent in renewable energy production and mining operations, we employ a rolling horizon optimization approach. Additionally, we integrate discrete event simulation to describe the whole process of ore processing to overcome the issue of missing parameters, enabling more accurate estimation of critical variables in the optimization problem. Preliminary results from this integrated approach demonstrate significant promise for the mining industry.

Game theory for the circular economy

Stream: Circular Economy, Remanufacturing and Recycling

Invited session

Chair: [Petr Fiala](#)

1 - Product recovery strategies considering competition: an analytical model

Song Liu, Maud Van den Broeke, Tanja Mlinar, Stefan Creemers

The rapid increase in waste from used products, coupled with growing environmental awareness, has encouraged original equipment manufacturers (OEMs) to collect and properly treat these used products through recycling, remanufacturing, or hybrid recovery strategies. Concurrently, independent remanufacturers (IRs) have begun entering the market to remanufacture used products. However, the effect of such industry competition on OEM's recovery strategies, consumer surplus and overall product returns remains unclear. In this study, we address these research questions by employing a stylised model in which an OEM faces competition from an IR, aiming to characterise optimal solutions for both parties. Our findings indicate that the entry of an IR positively influences the overall recovery of used products. Additionally, after the IR enters in the market, the OEM will be more reluctant to recover used products and less frequently opt for hybrid recovery strategies. Finally, through numerical analysis, we explore the variations in OEM's and IR's profits, and consumer surplus, across different scenarios.

2 - Delegate or Not? When Divisional Conflict Exists in Remanufacturing Operations

Qin Zhou, Fangsheng Ge

Alongside the practice of offering new and remanufactured products through distinct marketing channels, manufacturers have implemented diverse internal channel structures upon establishing a dedicated remanufacturing division. Some firms, like Caterpillar and Volvo Group, opt for a decentralized structure by delegating remanufacturing-related decisions to the dedicated division. In contrast, companies like General Electric and John Deere choose to retain decision-making at the firm level, encompassing both manufacturing and remanufacturing, following an integrated structure. Motivated by the observed industrial practices, we analytically investigate the manufacturer's internal channel structure decision within a manufacturer-retailer supply chain. Using a game theoretic model, our analysis demonstrates that while the decentralized structure encourages manufacturers to enter remanufacturing, the optimal approach is for manufacturers to choose the integrated structure when the production costs of new products are moderate. In

contrast, when the production costs of new products are polarized (i.e., either low or high), it is advantageous for decision-making authority to be delegated to the remanufacturing division. A triple-win outcome for the manufacturer, retailer, and remanufacturing division is unattainable because the retailer can never benefit from the manufacturer's decisions made under the decentralized structure.

3 - The optimal green product promotion strategy for omnichannel brand merchants

Wenting Han, Jianfeng Cai

Electronic coupons are a conventional tool used by brands to gain market share. However, with the rise of e-commerce live streaming, more and more brands are adopting AI live streaming as a new promotional method. In the context of sustainable development, AI live streaming will promote green products beyond geographical and language barriers. Therefore, integrating AI live streaming into product promotion has become a new direction to reveal the trade-offs between all-channel brands in AI live streaming and electronic coupon strategies. We develop a co-opetition model to compare the different promotion methods. In this model, we considered the potential impact of network externalities and consumer social responsibility. We found that although AI live-streaming promotion is widely used, its advantages are only evident when network externalities are significant. It is noteworthy that the intelligence level of AI anchors is closely related to the investment level of brand merchants, and differences in consumer social responsibility sensitivity may limit brand merchants' choices in AI live-streaming promotion strategies. In such cases, brand merchants may be more inclined to adopt electronic coupons, to increase sales revenue. Finally, we further examine the impact of logistics costs and the mixed promotion strategy on the sales revenue of supply chain members to show the robustness of the main findings.

4 - Closed-loop supply chain coordination with a deposit-refund system

Petr Fiala, Petr Pokorný

Traditional supply chain (SC) focuses on the management of forward flows going from upstream members to downstream units. The Closed-Loop Supply Chain (CLSC) also manages the backward flows from downstream members to upstream units. The integration of upstream and downstream activities into one system has three main objectives: to meet environmental objectives, to create new economic opportunities and to provide competitive advantages. This paper analyses a CLSC consisting of a manufacturer producing new products and selling them through a retailer. The manufacturer recycles the products at the end of their use (used packaging) and generates unit production cost savings if it uses recycled material instead of new material. The retailer sells the products to the final customer, collects the used packaging and returns the deposit to the customer under a guaranteed buyback contract. Several models are proposed for this situation and the operating conditions are analysed.

Sustainable Supply Chain Management

Stream: Sustainable Supply Chains

Invited session

Chair: [Selçuk Karabatı](#)

1 - Cooperative Adoption of Supply Chain Traceability

Sanjith Gopalakrishnan, Devpriyo Ray, Sriram Sankaranarayanan

Traceability — the ability to track products from origin to consumption — is viewed as an essential first step in effective control and compliance relating to environmental and labour obligations along the supply chain. Despite such benefits, the widespread adoption of traceability technologies in supply chains is hindered by challenges including the

high costs of adoption and the misalignment between entities incurring these costs and those reaping the benefits. We consider a network game-theoretic model of traceability technology adoption with possibly overlapping supply chains of multiple consumer-facing firms. We characterize the network-optimal adoption strategy with a tractable integer linear formulation. We then develop a cost sharing mechanism implementable via transfer payments to upstream suppliers. The cost sharing mechanism satisfies certain formal fairness properties, and, when efficient, supports the network optimal adoption strategy, and when inefficient, supports an equilibrium welfare which can be less than the network optimal welfare, and the ratio (a measure analogous to the price of anarchy for an associated non-cooperative game) is examined numerically using real-world supply chain structure data. A central theme of our work is to advance cost sharing, implementable via simple upstream transfer payments, as a complementary solution to the seeding strategy to initiate the diffusion of traceability technology in supply chains.

2 - Optimization of supply chain planning considering fair carbon emissions reduction and profit distributions

Chang Lyu, Songsong Liu

Facing the global challenge on climate change, how to maintain economic growth with effective carbon emissions reduction, has become an important and urgent issue. However, the related studies only focus on the unilateral optimization of total supply chain carbon emissions reduction, which will lead to uneven distribution of carbon emissions reduction among the supply chain members and seriously undermine the stability of the supply chain. To fill this research gap, this study establishes a trading path of carbon quota inside and outside the supply chain, and constructs a mixed integer linear programming (MILP) model for carbon emissions reduction based on the carbon cap-and-trade policy considering dual fairness. The production, distribution and capacity planning strategies, as well as carbon trading decisions, of all supply chain members are optimized. Using the Nash bargaining method and the ϵ -constraint method, the carbon emissions reduction and profit of each supply chain member can be fairly distributed. A industrial case based numerical example is introduced to demonstrate the applicability and effectiveness of the proposed model and solution method. The results show that Nash bargaining method could lead to a fair distribution of profit and carbon emissions reduction. In addition, when some members have insufficient carbon emissions allowance, the cap-sharing mechanism plays a better role in fair coordination.

3 - Product Line Design under Sustainability Incentives

Selçuk Karabatı, Burak Gokgur, Gunes Biliciler, Asli Gurler Kandemir

We examine the product line design and pricing problems faced by a firm when the standard and green products exhibit markedly different environmental performances. We assume that consumer valuations of the green product are influenced in part by their level of 'environmental awareness.' The market comprises two segments with varying levels of awareness. We introduce a utility-based consumer choice model and validate it through experimentation. Initially, we study the firm's profit maximization problem, and then integrate it into the regulatory agency's incentive design problem. The regulatory agency aims to achieve a predetermined reduction in the realized use-phase environmental impact of products. Through computational analyses, we highlight the significant impact of segment sizes and their levels of environmental awareness on both the product design decisions of the firm and the incentive design mechanism of the regulatory agency.

4 - Learning the effects of different buffering strategies in supply chain risk management: A regression approach

Emre Kara, Ali Tamer Unal

In today's globalized world, supply chains have global characteristics as well. Instead of geographically separated supply chains, there exists a global single supply chain in the world. Because of this circumstance, disruptions even at geographically distant locations can have severe impacts on all businesses globally. This nature of business increases the importance of supply chain risk management (SCRM) more than ever. Manufacturing plants require accurate tools to measure and manage risks effectively and profitably. In this study, an enhancement to Material Requirements Planning (MRP) type production

planning is proposed such that supply chain risk can be measured precisely and risk management policies can be developed accordingly. Initially, supply chain disruptions are defined and categorized and buffers used against these uncertainties are introduced to the MRP optimization model. With this new model and a risk function defined in terms of backlogs, an SCRM framework in the form of buffer management is proposed. Afterwards, the performance of the model with different settings is observed with simulation experiments and the statistical analysis is conducted on the data. Although the most significant buffering policy was found to be the supplier lead times, many findings were discovered on the effects of buffers on the supply chain (SC) risk and the profitability of the business.

Chair: *Ismail El Hallaoui*

1 - Local Branching techniques to strengthen Logic-Based Benders Decomposition

Ioannis Avgerinos, Yiannis Mourtos, Stavros Vatikiotis, Georgios Zois

This work focuses on the integration of Local Branching into Logic-Based Benders Decomposition (LBBDD) schemes. Given a MILP formulation for scheduling on unrelated parallel machines, it is noticed that certain k-OPT neighbourhoods could implicitly be explored by regular local search operators. After enumerating such neighbourhoods and obtaining their local optima, a local branching cut (applied as a Benders cut) eliminates all their solutions at once, thus avoiding an overload of the master problem with thousands of Benders cuts. To guarantee convergence to optimality, the constructed neighbourhood should be exhaustively explored - this procedure is accelerated by domination rules or selectively implemented on nodes which are more likely to reduce the optimality gap. In this study, we implement internal swaps of jobs, i.e. swaps between jobs on the same machine, over the solution of the master problem, to construct formulation-specific 4-OPT neighbourhoods. The experimentation on two challenging scheduling problems (i.e., the minimisation of total completion times and the minimisation of total tardiness on unrelated machines with sequence-dependent and resource-constrained setups) shows considerable reduction of optimality gaps or acceleration of convergence, in comparison with regular Benders cuts. As our approach is easily transferrable to different optimisation problems, it provides a promising prospect to improve the performance of regular LBBDD algorithms.

2 - Primal Benders Decomposition

Ismail El Hallaoui, El Mehdi Er Raqabi, Francois Soumis

Benders decomposition has been applied significantly to tackle large-scale optimization problems with complicating variables, which, when temporarily fixed, yield problems significantly easier to solve. Still, in its standard form, Benders decomposition shows several shortcomings, for instance upper bound zigzagging (for a minimization problem). We propose the Primal Benders Decomposition where the upper bound decreases at each iteration. It fully profits from primal information generally available in practice. As consequence, the number of cuts needed to converge is drastically reduced. Tests on large scale academic and industrial problems will be presented.

3 - Polynomial-size Formulation for Edge Coloring Problems on Forests

Emiliano Lancini, Michele Barbato

An edge coloring of a graph G is an assignment of colors to the edges so that two incident edges receive distinct colors. In particular, one is often interested in determining an actual edge coloring with the minimum number of colors so to explicitly assign tasks to machines over time. In the general case, this problem is known to be NP-Hard, however, if G is bipartite, one can solve this problem efficiently, through constructive algorithms. One drawback of this “algorithmic” approach is that it often involves sophisticated implementation. Moreover, finding edge coloring that minimize a generic objective function on bipartite graph is known to be NP-Hard.

The edge coloring Polytope of a graph G is the convex hull of all the possible edge coloring of G . In this work, we prove that a natural formulation of the edge coloring polytope on forests is polynomial in size and is described by a totally unimodular matrix. The interest towards this result is twofold. On one hand, it allows to use linear programming techniques to solve edge-coloring problems. On the other, it gives a polynomiality proof for all edge coloring problems on forests. Our results give an alternative proof to different known results such as the max-edge coloring problem on forests and the minimum-sum edge coloring on forests and multicycles.

4 - Formulations and Algorithms for the Edge Improvement Problems

Esra Koca, Burak Pac

We explore the edge improvement problem, relaxing the fixed edge traversal times assumption in traditional network flow problems. We consider two versions: discrete edge improvement, limited to a discrete set, and continuous edge improvement, where values can vary within a given range. Initially, we analyze both versions on a tree-shaped network, discussing their computational complexity. For more complex networks, we develop mixed-integer programming (MIP) formulations for both versions. This study is the first to propose and compare different formulations for the discrete edge improvement problem and to present one for the continuous version. Since our models underperform for medium and large problem instances, we introduce a Benders decomposition algorithm to solve the discrete problem. Additionally, we use it heuristically to find high-quality solutions for the continuous edge improvement problem efficiently. We also devise an MIP formulation to determine lower bounds for the continuous problem, leveraging McCormick envelopes and optimal solution properties. Our experiments show that the Benders decomposition algorithm outperforms other formulations for the discrete edge improvement problem, while the heuristic method proposed for the continuous problem provides quite good results even for large instances.

Optimization problems in scheduling

Stream: Combinatorial Optimization

Invited session

Chair: M. Grazia Speranza

1 - Technician Routing and Scheduling for Tasks with Uncertain Resolution Locations

Siv Sørensen, David Pisinger

We introduce a new extension of the Technician Routing and Scheduling Problem (TRSP), where tasks are associated with multiple potential resolution locations, each with a distinct probability of success. Our objective is to efficiently resolve all tasks while minimizing resource consumption, such as driving distance or time. We investigate various routing and scheduling strategies and compare their performance against a known brute force approach employed in the telecommunication sector. Additionally, we model the problem as a Markov Decision Process (MDP) to find an optimal decision making policy for the technicians, that minimizes the expected resource consumption for

solving all tasks. We will also analyze a range of ‘what if’ scenarios, where we relax common problem constraints such as technicians having to finish their current task before starting another. Computational results are reported for simulated scenarios with a varying number of technicians, resolution locations, and tasks, along with different spatial configurations of the resolution locations for each task.

2 - Resource constrained project scheduling with durational uncertainties and maximum time lags

Evelin Szögi, Péter Györgyi, Tamas Kis

We study a resource constrained project scheduling problem. A set of jobs arrive in real-time and each of them is a sequence of tasks that require several resources for execution. There are minimum and maximum time lag constraints among the consecutive tasks, which may have uncertain durations. The objective is to minimize the total waiting time so that we guarantee the feasibility of the resulting schedule. The problem has a great practical interest in small-scale biomanufacturing systems, such as laboratory for drug design, where there can be large uncertainties in the duration of the tasks. For instance, the production of CAR T cells for personalized gene therapies of patients with a serious disease. The production process requires several steps including cell expansion where millions of CAR T cells are grown in a cell culture. The variance of cell expansion time may be several days, while the other production steps are deterministic and take a couple of days. We have the following results: 1) We provide theoretical bounds about the quality of solutions we may expect. 2) We propose a polynomial time reactive scheduling policy for inserting tasks into a schedule. This method (i) can handle large instances, (ii) outperforms a simple heuristic with the feasibility guarantee, and (iii) starts each job as early as possible relative to the previously scheduled jobs.

Ack.: This work has been supported by the H2020 project AIDPATH, grant agreement number 101016909.

3 - The LPT heuristic for minimizing total load on a proportionate openshop

Gur Mosheiov, Enrique Gerstl

The LPT heuristic for minimizing total load on a proportionate openshop

Enrique Gerstl and Gur Mosheiov

School of Business Administration, The Hebrew University, Jerusalem 91905, Israel

Abstract

We study the problem of minimizing total load on a proportionate openshop. The problem is proved to be NP-hard. A simple LPT (Longest Processing Time first)-based heuristic is proposed, and a bound on the worst-case relative error is introduced. The proposed bound is significantly smaller than the classical bound on the relative error of LPT when minimizing makespan on parallel identical machines. The algorithm is tested numerically and is shown to produce extremely close-to-optimal schedules.

4 - Optimizing paths and schedules in crowded events

Valentina Morandi, Gianfranco Guastaroba, M. Grazia Speranza

In large events, improving visitor experiences involves a personalized planner for individual preferences. Crafting unique itineraries, it often overlooks suggestions given to others visitors. This is crucial in limited-capacity locations, as myopic decisions may lead to extended queues. We study a situation where a large number of people visit a popular venue (e.g., an art gallery, a mall, a theme park, or an exhibition) where points of interest are located (e.g., paintings, shops, attractions, or pavilions). Visitors have a maximum time available for the overall experience. The points of interest have a binding capacity and, whenever the turnout of visitors exceeds such capacity, queues occur. Given the maximum time available along with the time spent queuing, a selection of the points of interest may become necessary. Visitors usually act as autonomous decision-makers and do not take into account their interaction with other visitors. This leads to remarkable inefficiencies that could be, to a certain extent, overcome through a coordination of the paths and schedules of the different visitors. The resulting optimization problem is modeled on a time-space network

as a Mixed-Integer Linear Program (MILP), where the goal is to minimize a weighted combination of the points of interest not selected and the time spent queuing. Computational results show the benefits that can be achieved by using the model proposed as a tool to support decision-making.

1 - Where am I in the course? Student-facing dashboard for Conceptual Modeling Education

Elena Tiukhova, Charlotte Verbruggen, Tinne De Laet, Bart Baesens, Monique Snoeck

Modern technologies make it possible to collect and analyze large amounts of educational data. Learning Analytics (LA) uses this data to improve learning. To deliver LA insights to the educational stakeholders, Learning Analytics Dashboards (LADs) aggregate learning metrics into a single screen using a variety of visualization techniques. A learner must be provided with a frame of reference for proper data interpretation, with peers being the most popular choice in modern LADs. However, it carries the risk of negatively impacting learners by encouraging competition rather than mastery of knowledge, thereby widening the gap between high-performing and struggling learners. This problem is exacerbated in conceptual modeling education, where mastery orientation is crucial to learn to solve complex task of modeling. This research presents a student-facing LAD, grounded in achievement goal orientation theory, with the primary goal of supporting mastery orientation (task completion/understanding). The LAD also supports performance goal orientation (social comparison) through an optional peer comparison feature. By monitoring dashboard usage, student activity, and academic performance, our study investigates (RQ1) the added value of the LAD to student activity and performance in conceptual modeling education, (RQ2) the relationship between dashboard usage and learning orientation, and (RQ3) the added value of the performance-oriented component to student activity and performance.

2 - Sequence mining algorithm for students failure classification in multiple blended courses scenarios

Joaquín Roa, Cecilia Saint-Pierre, Thomas Peet

Over the past decade, the use of learning management systems (LMS) for online and blended courses has become widespread in higher education institutions, resulting in a high increase in the available data. The unprecedented volume of data has allowed researchers to develop new and improved algorithms for monitoring the learning process, becoming a useful tool for teachers, given the absence of face-to-face interaction with the students. In our work, we developed a new iteration of a classification method that uses sequence mining from event log data to predict lower-performing students during the realization of a course. Previous versions of this algorithm were based on non-continuous scenarios, using data available for various courses during a single semester. In the present study, we made optimizations to the algorithm, considering a greater diversity in the available training data, fine-tuned using performance metrics that minimize false negatives, and delimited a new, more general methodology, for present and future use cases. We tested our enhanced method in a second-year undergraduate blended course from the Engineering School at Universidad de Chile, with online content, activities, and assessments supported in

the institutional LMS. Results show that the enhanced algorithm improves both accuracy and recall, allowing professors to identify the segment of lower-performance students before the course concludes, allowing for proactive measures to be taken.

3 - A network-based recommender system to enhance learning in educational games

Eva Ósk Gunnarsdóttir, Anna Ingólfssdóttir, Antonio Puron, María Óskarsdóttir, Sebastian Maldonado

Educational games hold particular significance in elementary school education, as they serve as a popular tool for engaging children in learning. However, a common challenge faced by these platforms is the risk of children becoming disinterested. To mitigate this, it becomes desirable to sustain their engagement with the platform to foster continuous learning and retention. This raises the crucial question: Which games should children play? While the approach may be effective in the classroom, children who engage with these games outside of school settings have unrestricted access to all available games, often without knowing which ones are best suited to their needs. Consequently, if they struggle, they are prone to becoming bored or frustrated, ultimately leading them to disengage. To enhance engagement and optimize learning outcomes, it is essential for children to play games where they perform adequately yet are still challenged enough to promote learning. In this work, we develop state-of-the-art recommender systems based on graph-based neural networks for an educational game platform for children called Tak-Tak-Tak. The machine learning process is guided by the choices made by the users in terms of the next game to play, as well as the efficacy of a user's learning experience within a game and the duration of the play sessions. We conduct a comparative analysis between a wide variety of recommender system approaches to evaluate their effectiveness in this context.

1 - Solving scheduling problems in real-time through deep learning methods

Imanol Echeverria, Roberto Santana, Maialen Murua

Recently, deep reinforcement learning (DRL) has been applied to solve scheduling problems in real-time. These methods involve generating a policy through interaction with thousands of random instances, leading to enhanced solutions by maximizing a reward. However, real-world instances often exhibit repetitive patterns and represent only a small subset of all possible scenarios. Additionally, obtaining a large number of examples is uncommon in real-world applications. In this paper, we propose a methodology to learn an optimized dispatching rule tailored to a specific set of instances. To do this, we model the scheduling problem as a Markov process, employ graph neural networks to represent instances, and utilize behavioral cloning alongside optimal solutions to simpler instances to determine the best policy. Given the challenge of training with limited instances, we suggest initially training a general scheduler using diverse instances. Subsequently, this model undergoes retraining to adapt to specific distributions, involving fine-tuning of its last layers for efficient adaptation. To validate our approach, we conduct experiments on both the job-shop scheduling problem (JSSP) and

the flexible JSSP in several public scheduling benchmarks. Results demonstrate that our method, trained using behavioral cloning, outperforms DRL-trained models. Additionally, we show that the retraining strategy enables superior performance compared to a general model trained with random instances.

2 - A network clustering model for multiple selection questions in opinion surveys

Stefano Benati, Justo Puerto

Opinion surveys can contain closed questions to which respondents can give multiple answers. We propose to model these data as networks in which vertices are the eligible items and arcs are the respondents. This representation opens up the possibility of using complex networks methodologies to retrieve information and most prominently, the possibility of using clustering/community detection techniques to reduce data complexity. We will take advantage of the implicit null hypothesis of the modularity function, namely, that items are chosen without any preferential pairing, to show how the hypothesis can be tested through the usual calculation of p-values. We illustrate the methodology with an application to Eurobarometer data. There, a question about national concerns can receive up to two selections. We will show that community clustering groups together concerns that can be interpreted in a consistent way and in general terms, such as Economy, or Security or Welfare issues. Moreover, we will show how different society groups are worried by different class of items.

3 - Refining the performance metrics and related mathematical operators for ordinal classification problems

Sajid Siraj, Edward Abel

In multilabel classification (MLC) problems, the standard confusion matrix is generally replaced by a set of confusion matrices, with one matrix per label. Although ordinal classification problems are slightly different from MLC, it shares the same set of performance metrics used for MLC. We contend that ordinal classification has nuances which makes it different from MLC. As in binary classification, the notion of false positive and false negative are still valid in MLC problems in a sense that any wrongly predicted label can be termed as false positive (or false negative). However, in ordinal classification, these notions are replaced by overestimates and underestimates. We propose the use of different mathematical operators to quantify the strength of overestimates and underestimates. The proposed metrics tailored for ordinal classifiers not only introduces a novel framework for evaluation but also signifies a crucial step forward in enhancing the performance evaluation of ordinal classification algorithms. We demonstrate its practical usefulness with the help of a number of case studies.

4 - Outranking hypercuboid learning approach for classification problems

Nabil Belacel

Classifiers in today's data-driven domain face myriad challenges: overfitting, computational overheads, diminished accuracy, imbalanced datasets, and the opaque "black box" issue. Conventional classifiers struggle with managing noisy and missing features. This study introduces classification methods leveraging hypercuboid learning and outranking measures. Our framework autonomously discerns hypercuboid features from the training set, eliminating the need for prior domain expertise. These hypercuboids capture essential dataset patterns, while outranking measures mitigate noise and uncertainty. Empirical evaluations across diverse datasets from the UCI repository compare the proposed classifiers with established models like k-NN, SVM, Random Forest, Neural Networks, and Naive Bayes. Results demonstrate our classifiers' robustness against imbalanced data and extraneous features, achieving comparable or superior performance to benchmarks. Moreover, our models offer interpretability without sacrificing predictive accuracy.

1 - Integrated Regenerator Planning and RWA in WDM Optical Networks under Link Failures

Kai Pan, Chong Wang, Bin Tian, Junyan Liu, Fan Zhang

The widespread deployment of wireless telecommunication networks and growing Internet traffic globally leads to a substantial increase in signal traffic demands in fiber optic networks. This demand surge places significant pressure on the survivability of optical networks, specifically when faced with fiber cable failures. To address this challenge, in this paper, we consider integrated planning of regenerator installation, optical connection routing, and wavelength assignment (RWA) for wavelength division multiplexing (WDM) optical networks under link failures. We minimize the number of backup regenerators required to fulfill all connection requests under all potential link failures while accounting for the wavelength and routing constraints. We formulate the problem as an integer program, while its size exponentially increases with the network size by nature. To solve large-scale instances for practical uses in the industry, we propose efficient algorithms to generate near-optimal solutions that are practically implementable. We perform extensive numerical experiments to demonstrate the effectiveness of our approach in solving real-world instances provided by our industry partners. The results show that our approach can efficiently obtain high-quality solutions while ensuring a minimal increase in backup regenerators as the network grows. Our solutions also offer valuable insights into planning a cost-effective and reliable fiber optic network for network operators.

2 - Recent Advances in Solving Large-Scale Optimizations from an Industry Perspective

Fan Zhang, Yingying Cheng, Jiazheng Wang, Junyan Liu, Yongfeng Li, Jie Sun, Jianshu Li, Kun Mao

In this talk, we introduce large-scale mathematical optimization problems that arise within the complex landscape of the information and communication industry. Our focus spans several practical scenarios, including resource allocation in large scale data networks, traffic planning in optical networks, as well as task allocation and scheduling in deployment operations. These optimization challenges predominantly fall into the categories of LP or MILP. The scale of these problems varies significantly, ranging from millions to billions of variables and constraints. Some medium-sized problems necessitate real-time decision-making, with solving times in milliseconds to seconds. The larger problems demand hours of computational effort for offline planning. The stringent requirement poses considerable challenges, especially given the constraints of single-server computational resources. We aim to strike a balance between customized and generic design approaches across multiple dimensions, including optimality, efficiency, robustness, and generality. Leveraging Huawei's OptVerse optimization solver, the design solution directly translates to increased revenue or reduced costs. Additionally, some contributions further enhance OptVerse's generic problem-solving performance. Lastly, we explore the concept of co-optimization of software and hardware—a new dimension that promises innovative solution design, novel development modes, and potential business models for future solvers.

3 - Solving LP Relaxations for Routing and Wavelength Assignment Problem with Partial Path Protection

Zhou Xu, Xianyan Yang, Junyan Liu, Fan Zhang, Fabo Sun, Feng Li

This paper studies a routing and wavelength assignment problem for an optical-fiber telecommunication network, known as the RWAP with

partial path protection (RWAP-PPP). The existing literature lacks any studies on its relaxations. As a result, the quality of solutions to the RWAP-PPP cannot be properly measured, which is critical to telecommunication service providers in their bidding to customers, and in their determination of service improvements. We derive and compare various linear programming (LP) relaxations of the RWAP-PPP, from which we propose a novel LP relaxation that can be efficiently solved by a Benders decomposition algorithm to produce good lower bounds for the RWAP-PPP. Computational results show that the newly proposed LP relaxation can be solved efficiently, even for some large-scale practical networks of hundreds of nodes and thousands of requests.

4 - Bifurcation behaviors shape how continuous physical dynamics solves discrete Ising optimization

Jie Sun

Simulating physical dynamics to solve hard combinatorial optimization has proven effective for medium- to large-scale problems. The dynamics of such systems is continuous, with no guarantee of finding optimal solutions of the original discrete problem. We investigate the open question of when simulated physical solvers solve discrete optimizations correctly. Having established the existence of an exact mapping between CIM dynamics and discrete Ising optimization, we report two fundamentally distinct bifurcation behaviors of the Ising dynamics at the first bifurcation point: either all nodal states simultaneously deviate from zero (synchronized bifurcation) or undergo a cascade of such deviations (retarded bifurcation). For synchronized bifurcation, we prove that when the nodal states are uniformly bounded away from the origin, they contain sufficient information for exactly solving the Ising problem. When the exact mapping conditions are violated, subsequent bifurcations become necessary and often cause slow convergence. Inspired by those findings, we devise a trapping-and-correction (TAC) technique to accelerate dynamics-based Ising solvers, including CIMs and simulated bifurcation. TAC takes advantage of early bifurcated "trapped nodes" which maintain their sign throughout the Ising dynamics to reduce computation time effectively. Using problem instances from open benchmark and random Ising models, we validate the superior convergence and accuracy of TAC.

of [U+202F]Operations Research: code generation to increase productivity, chatbots for documentation, generation of optimization models - just [U+202F]to name a few. Thinking further, an LLM may generate models for decision support tools and execute the code to guide complex business decisions: a CO₂-optimal delivery network, an optimal production schedule, an optimized pricing table. Large language models (LLMs) occasionally produce incorrect or misleading results, a phenomenon commonly called "hallucinations". We demonstrate basic examples where a slight adaptation of a question (prompt) turns the LLM response into a false statement. Besides basic inaccuracies, there are also considerations around data exposure, data leakage, privacy violations, copyright violations, biased answers, dangerous or unethical usage, inappropriate language and malicious code. Best practices need to be followed to responsibly apply GenAI in decision support tools! Our examples demonstrate the importance of balancing innovation with risk mitigation in leveraging GenAI for critical decision-making tasks advocating for a holistic approach that combines technological advancements with ethical considerations and human oversight.

3 - Automatic model decomposition in Hexaly Optimizer

Julien Darlay

Hexaly Optimizer, formerly known as LocalSolver, is a model and run solver that integrates heuristics and exact methods. A set-based modeling formalism was introduced to simplify the modeling of certain combinatorial problems like routing or packing problems. For instance, in a routing problem, list variables can be used to model the sequence of visits made by each truck. These decision variables are well suited for a heuristic search but are much more difficult to integrate in a mathematical programming approach to compute lower bounds. A direct reformulation in a MILP model introduces a quadratic number of binary decisions with several big M constraints leading to poor scalability and bounds. Hexaly 13.0 automatically detects such structures in a user model and reformulates them in an extended MILP model to compute lower bounds. This model is solved efficiently using state of the art branch-cut-and-price techniques from the literature. This talk will present the general approach and the algorithms used for the resolution and some benchmarks on the CVRP library.

1 - Gurobi OptiMods - Painless Optimization Templates

Matthias Miltenberger

One of the most important aspects of mathematical optimization and Operations Research is getting your data into a form that optimization solvers can understand and work with. The "art of modeling", as it is often referred to, can all too easily get in the way of actually solving the problem at hand. Gurobi's open-source OptiMods are data-driven Python APIs for different common optimization use cases. They enable practitioners and learners alike to compute solutions without requiring extensive modeling experience. This session presents the goals and design of the project and explains how to use and extend it.

2 - Generative AI in Decision Support Tools: Managing Hallucinations

Oliver Bastert, Jens Schulz

The field of generative artificial intelligence (GenAI) has seen exponential growth over the past few years in research papers and publications. The techniques have gained traction across industries. A hype train is rolling around how to best [U+202F]leverage GenAI in the field

4 - VIVA: A web-based tool for analyzing and visualizing optimization solver benchmarking results

Andreas Lundell, Oscar Härtull, Alireza Olama

When developing software for solving various classes of optimization problems, e.g., MILP, and MINLP, it is crucial to have tools for comparing the impact of new functionality. The performance can be measured using many different metrics including solution time and quality of the solution, so it is not always trivial to assess the added value. It is also important for end users to be able to compare the performance of available optimization solvers when selecting which one to use. So far, available tools for performing such analysis have been mainly static, i.e., there have been limited options for the users to interact, filter, and sort the results.

In this presentation, we introduce a tool called VIVA (Visualize, Interact, Verify, and Analyze Benchmarking Data for Optimization Solvers) for comparing the performance of optimization solvers in an efficient and user-friendly way. VIVA is an open-source project implemented in TypeScript and generally based on standardized web technologies. This means that VIVA can be used directly in a web browser without installing and configuring additional dependencies. Currently, VIVA implements most of the functionality of the Python-based PAVER tool, including its visualization capabilities, but the open framework of VIVA means it can be extended further in the future.

To illustrate the capabilities of VIVA, the tool is also demonstrated on recent benchmark results from convex and nonconvex MINLP solvers during the presentation.

1 - Profit-driven churn prevention through predict-and-optimize

Nuria Gómez-Vargas, Sebastian Maldonado, Carla Vairetti

In this work, we introduce a novel predict-and-optimize method for profit-driven churn prevention. We frame the task of targeting customers for a retention campaign as a regret minimization problem. The main objective is to leverage individual customer lifetime values (CLVs) to ensure that only the most valuable customers are targeted. In contrast, many profit-driven strategies focus on churn probabilities while considering average CLVs. This often results in significant information loss due to data aggregation. Our proposed model aligns with the guidelines of Predict-and-Optimize (PnO) frameworks and can be efficiently solved using stochastic gradient descent methods.

2 - Harnessing spatial granularity in boosted tree models for house price prediction

Margot Geerts, Seppe vanden Broucke, Jochen De Weerd

Spatial relations in data such as house prices are known to vary strongly depending on their location. Several modeling techniques have been proposed from the domain of spatial statistics such as geographically weighted regression. This technique addresses this problem by allowing to vary the parameters over space. Nevertheless, more recent machine learning methods such as gradient boosted trees perform better in terms of prediction and improve scalability towards large datasets significantly. Nevertheless, global tree-based models, trained over the complete spatial region of the dataset, present large local errors which indicate their flawed ability to model spatially varying relations in the data. A solution consisting in learning local models on spatial partitions of the dataset is not preferred due to the loss of information shared by the partitions. In this study, we confirm the presence of this phenomenon in a real-life house price dataset and explore pathways towards a unification of global and local models to address this problem.

3 - Container dwell time prediction considering feature engineering and feature selection

Mahdi Jahangard, Ying Xie

Container dwell time prediction plays a crucial role in optimizing logistics and supply chain operations at ports and container terminals. Accurate predictions of such an indicator can enhance resource allocation, reduce congestion, and improve overall efficiency at the point of the global trade network. Data preprocessing and feature selection are critical steps in developing robust and efficient predictive models. This study develops feature engineering not only for structured data but also for unstructured data where a textual feature is classified through GloVe word embeddings and Cosine similarity to leverage the strengths of both types of data into machine learning methods. In addition, various feature selection techniques such as Filter methods, Embedded methods, and Wrapper methods are applied to identify the most influential factors affecting container dwell time, ultimately selecting 12 out of the 19 features for prediction. Instead of developing a regression model to predict dwell time, we classify dwell time based on data distribution into two and three classes, highlighting the significance of dwell time ranges over singular values. Random Forest and XG-Boost algorithms are employed for the classification, where the former outperforms in terms of accuracy. From an operational point of view, the results of classification can facilitate effective decision-making for operational management such as equipment scheduling, yard stacking planning, workload planning, etc.

4 - Enhancing Environmental Impact Assessment Procedures in Chile: Multi-Label Transformer Models for Predicting State Agencies Participation

Alonso Leal, Carla Vairetti, Sebastian Maldonado

In Chile, the Environmental Impact Service (SEA) mandates assessments for industrial projects falling under specific categories, necessitating either an Environmental Impact Study (EIA) or an Environmental Impact Declaration (DIA). Central to the evaluation process is the invitation of the correct state administration agencies for participation. This investigation presents a novel approach leveraging pre-trained transformer models, tailored to predict the involvement of various state bodies in project assessments. Through the analysis of text within the project's primary form of declaration, we curated a dataset capturing participation patterns. Secondly, we fine-tuned the transformers to yield multi-label predictions, this was done by the modification of the final transformer layer, which facilitated the output of probabilistic estimates for each agency's participation. To address class imbalance in the dataset, we integrated class weights techniques into the loss function during model training. The experimental results showcase the effectiveness of this approach in accurately predicting multi-label participation, thereby enhancing the decision-making process surrounding environmental impact assessments. This research contributes to refining the SEAs procedures, ensuring comprehensive participation and evaluations of industrial projects by state agencies.

Adaptive and Polyak step-size methods

Stream: Advances in large scale nonlinear optimization
Invited session

Chair: Dmitry Kamzolov

Chair: Martin Takac

1 - On the Stochastic Polyak Step Size for Machine Learning: Proximal and Momentum Versions

Fabian Schaipp

In this talk, we show how to combine the stochastic Polyak step size with established practical techniques such as regularization and momentum. In particular, we derive a proximal version of the Polyak step size, and a momentum version which we call MoMo. MoMo can be seen as an adaptive learning rate for SGD with momentum; in fact we can derive a MoMo version of any momentum method, most importantly MoMo-Adam. These derivations are possible through the connection between the Polyak step size and model-based stochastic optimization, where the model is truncated at a known lower bound. In machine learning, such lower bounds are typically known. By construction, our new adaptive learning rates reduce the amount of learning-rate tuning, which is demonstrated through deep learning experiments on the CIFAR, Imagenet, Criteo, and IWSLT14 dataset.

2 - Unveiling the Power of Adaptive Methods Over SGD: A Parameter-Agnostic Perspective

Xiang Li

Adaptive gradient methods are popular in optimizing modern machine learning models, yet their theoretical benefits over vanilla Stochastic Gradient Descent (SGD) remain unclear. This presentation examines the convergence of SGD and adaptive gradient methods when optimizing stochastic nonconvex functions without the need for setting algorithm hyper-parameters based on problem-specific knowledge. First, we explore smooth functions and compare SGD to well-known adaptive methods like AdaGrad, Normalized SGD with Momentum (NSGD-M), and AMSGrad. Our findings reveal that while untuned SGD can reach the optimal convergence rate, it comes at the expense of an unavoidable catastrophic exponential dependence on the

smoothness constant. Adaptive methods, on the other hand, eliminate this reliance without needing to know the smoothness constant in advance. We then look at a broader group of functions characterized by (L0, L1) smoothness. Here, SGD is shown to fail without proper tuning. We present the first instance of tuning-free convergence with adaptive methods in this context, specifically with NSGD-M, achieving near-optimal rate despite an exponential dependence on the L1 constant. We also demonstrate that this dependency is unavoidable for a family of normalized momentum methods.

3 - EXTRA-NEWTON: A First Approach to Noise-Adaptive Accelerated Second-Order Methods

Kimón Antonakopoulos

This work proposes a universal and adaptive second-order method for minimizing second-order smooth, convex functions. Our algorithm achieves optimal convergence rate when the oracle feedback is stochastic with variance, and improves its speed of convergence when it is run with deterministic oracles, where \mathcal{I} is the number of iterations. Our method also interpolates these rates without knowing the nature of the oracle a priori, which is enabled by a parameter-free adaptive step-size that is oblivious to the knowledge of smoothness modulus, variance bounds and the diameter of the constrained set. Building on this machinery, we show that we may be able to extract asymptotically faster rates than the standard Nesterov's accelerated second order methods.

4 - AdaBatchGrad: Combining Adaptive Batch Size and Adaptive Step Size

Petr Ostroukhov

This work presents a novel adaptation of the Stochastic Gradient Descent (SGD), termed AdaBatchGrad. This modification seamlessly integrates an adaptive step size with an adjustable batch size. An increase in batch size and a decrease in step size are well-known techniques to "tighten" the area of convergence of SGD and decrease its variance. A range of studies by R. Byrd and J. Nocedal introduced various testing techniques to assess the quality of mini-batch gradient approximations and choose the appropriate batch sizes at every step. Methods that utilized exact tests were observed to converge sublinearly. Conversely, inexact test implementations sometimes resulted in non-convergence and erratic performance. To address these challenges, AdaBatchGrad incorporates both adaptive batch and step sizes, enhancing the method's robustness and stability. This makes AdaBatchGrad markedly more robust and computationally efficient relative to prevailing methods. To substantiate the efficacy of our method, we experimentally show, how the introduction of adaptive step size and adaptive batch size gradually improves the performance of regular SGD. The results imply that AdaBatchGrad surpasses alternative methods, especially when applied to inexact tests.

into mixed-integer-linear programs (MILP) have been developed. Decision Programming (Salo et al., EJOR 299/2, 2022) enforces constraints on different possible realizations of the whole problem. This exposes the full probability distribution of consequences to be used in the optimization model, which in turn allows risk to be explicitly constrained or optimized. Rooted junction tree approach (Parmentier et al., *Informatics Journal on Optimization*, 2/3, 2020) decomposes an influence diagram into clusters, that are subsets of nodes, and finds the probability distributions of these clusters with a MILP. Compared to decision programming, the rooted junction tree model offers better computational performance, but risk cannot be straightforwardly represented in the optimization model. We present approaches and conditions that combine the computational efficiency of rooted junction trees and the modeling flexibility of decision programming. More specifically, we highlight how risk can be directly represented in rooted junction tree models with examples.

2 - Mixed-integer reformulations for influence diagrams with conditional information structures

Olli Herrala, Fabricio Oliveira, Tommi Ekelholm

Endogenous, or decision-dependent, uncertainties pose significant challenges for decision making under uncertainty. Various methods have been developed for different types of endogenous uncertainty, including influence diagrams (ID) for intuitively representing decision-dependent probability distributions. If the problem instead has a decision-dependent information structure, that is, some of the information is revealed conditionally, conditional non-anticipativity constraints can be added to a stochastic programming model representing the problem. However, combining these two types of uncertainty has proven challenging, and no framework existed for such problems until recently. This presentation aims to shed light on two approaches for reformulating an influence diagram as a mixed-integer linear problem (MILP), enabling us to simultaneously consider different types of endogenous uncertainty and risk measures. A framework called Decision Programming directly reformulates the ID into a MILP, but it has been shown that first reformulating the ID into a rooted junction tree can greatly enhance computational performance and result in asymptotically smaller MILPs. Our discussion is focused on a Julia package implementing the framework along with possible improvements, and an illustrative climate change mitigation case study. Additionally, we mention some other application areas where the methods have been applied to give the audience an overview of the possibilities.

3 - Algorithmic Advances for Influence Diagrams

Radu Marinescu, Junkyu Lee, Rina Dechter, Bobak Pezeshki, Alex Ihler

Influence diagrams provide a modeling and inference framework for sequential decision problems, representing the probabilistic knowledge by a Bayesian network and the preferences of an agent by utility functions over the random variables and decision variables. Computing the maximum expected utility (MEU) and the optimizing policy is exponential in the constrained induced width of the model and it has been long recognized as one of the most difficult probabilistic inference tasks, especially for larger problem instances. We will overview a suite of exact and approximate inference algorithms for IDs developed over the past years, starting with variable elimination (VE) schemes that use local computations to solve IDs exactly, and continuing with variational approaches based on message-passing over join-graph decompositions and weighted mini-buckets that yield variational bounds on the MEU and sub-optimal decision policies. We will also show that the latter bounding schemes can be used as heuristics generators that can guide efficient search strategies such as AND/OR search for solving IDs exactly that exploit the underlying structure of the model. We will provide experimental results on various synthetic and real-world benchmarks for IDs to highlight the performance of the inference methods presented. Finally, we will discuss recent extensions of IDs for decision making with imprecise information, multiple objectives and the potential of augmenting IDs with causal semantics.

4 - Optimal Testing Strategies for Information Acquisition in Decision Programming

Decision problems represented as influence diagrams

Stream: Stochastic, Robust and Distributionally Robust Optimization

Invited session

Chair: *Milos Kopa*

Chair: *Ahti Salo*

1 - Risk averse mixed-integer linear programming models for influence diagrams

Topias Terho, Olli Herrala, Fabricio Oliveira

Influence diagrams are an intuitive representation of decision problems with dependencies between uncertain events, decisions, and consequences. Recently, two frameworks that transform influence diagrams

In the context of influence diagrams, we formalise the notion of information decisions which are associated with decision nodes that determine what information will be acquired to support decisions at a given decision node later; or, more specifically, what is the set of nodes whose states are known when making this later decision. Examples of such information decisions include choices among diagnostic tests because testing decisions determine what test results will be available when making treatment decisions, for instance. For the development of optimal strategies, we build on Decision Programming (Salo et al., EJOR 299/2, 2022) in which the influence diagram is solved by converting it into an equivalent mixed-integer linear programming (MILP) problem; this makes it possible to solve influence diagrams which do not fulfil the usual 'no-forgetting' assumption, or which involve logical, resource, or risk constraints that preclude the use of common solution approaches such as arc reversals and node removals. We present optimization formulations that employ binary variables to represent information decisions. We also provide numerical examples to illustrate the development of optimal testing strategies for information acquisition.

Data Valuation from Data-driven Optimization

Stream: Stochastic, Robust and Distributionally Robust Optimization

Invited session

Chair: Juan Miguel Morales

Chair: Robert Mieth

1 - Wasserstein Distance Based Market for Differentially-Private Data Trading

Fei Teng, Saurab Chhachhi

Data is increasingly vital to deal with the increased intermittency and limited controllability of renewable and distributed energy resources. Concurrently, data sharing raises privacy concerns motivating the need for privacy-enhancing techniques such as differential privacy. Data markets provide a means to enable wider access as well as determine the appropriate privacy-utility trade-off. Existing data market frameworks either require a trusted entity to perform computationally expensive valuations or are unable to capture the combinatorial nature of data value and do not endogenously model the effect of differential privacy. We address these shortcomings by proposing a valuation mechanism based on the Wasserstein Distance for differentially-private data, and two procurement mechanisms leveraging incentive mechanism design theory for task-agnostic data procurement, and task-specific joint task and data optimisation. The latter are reformulated into tractable mixed-integer second-order cone programs. The framework is applied to develop a joint energy and data market. We consider the retailer energy procurement problem where consumers' demand is uncertain and historical demand data is differentially-private. This is modelled as an integrated forecasting and optimisation problem providing a means of valuing data directly rather than forecasts or accuracy. The value of joint energy/data clearing are highlighted through extensive numerical studies using real smart meter data.

2 - Regression Markets: Incentivizing Data Sharing for Forecasting

Thomas Falconer, Jalal Kazempour, Pierre Pinson

Machine learning tasks rely heavily on the quality of input data, yet acquiring adequate datasets can often be challenging. Useful datasets are typically distributed amongst various owners who may, in practice, be competitors in downstream markets, making them reluctant to share information. In contrast to existing frameworks that address distributed and privacy-preserving (incentive-free) learning, we explore

here a novel market-based framework, called regression markets, to provide financial incentives for data sharing. Agents aiming to improve their forecasts can post a regression task, for which others can contribute by sharing their data and get monetarily rewarded for it. We introduce the market design, provide its desirable properties, and discuss some of the open challenges with practical applications of treating data as a tradeable good.

3 - Defining and Quantifying the Marginal Value of a Data Set via Distributionally Robust Optimization

Juan Miguel Morales, Robert Mieth, Adrián Esteban-Pérez

Data-driven stochastic optimization has empowered decision-making by providing an effective way to exploit data to tackle complex problems in many domains. However, there is still a lack of theory and methods to quantify the sensitivity of the decision cost to the natural input to stochastic optimization, namely, the data set. In this talk we show that Distributionally Robust Optimization (DRO) offers a natural framework to perform this sensitivity analysis by establishing the notion of marginal value of the quality of a data set. We discuss the ability of the Wasserstein metric to encode data quality and then introduce a Wasserstein DRO formulation to compute the marginal value of data sets from multiple sources or providers that may refer to the same uncertain input parameter and/or to different ones.

4 - Data value at the grid-edge

Robert Mieth

This talk presents an approach to quantify the value of data sets available to the operator of an electric distribution system that seeks to compute optimal control setpoints for distributed energy resources. We leverage the ability of the Wasserstein metric to encode the quality of available data sets and present a modification of a data-driven AC optimal power flow problem with stochastic load and renewable energy injections that can internalize this data quality information. The proposed approach offers an effective tool for the system operator to handle data sets of varying quality, e.g., due to the necessary privacy protection or aggregation of data collected at the grid edge. We show that this not only helps the system operator to improve operations with existing data, but also informs planning decisions for investments in advanced data collection and communication technology.

1 - Platform Finance and Channel Strategies of Dual Channels

Nina Yan

In the platform economy, e-commerce platforms serve as distribution channels and financing providers through online loans. This study focuses on platform finance, where credit lines or interest rates are set, offering limited or unlimited loans to capital-constrained sellers. The optimal sellers' channel strategy (single, online-dominant, or offline-dominant dual channels) depends on the platform's credit line, consumers' channel preferences, and switching behavior. With unlimited (or limited) loans, the seller's dominated channel's quantity decreases (or increases) with initial capital. Preferences for unlimited or limited loans depend on the dominant channel and capital constraints. Loan offerings lead to Pareto improvements for both sellers and platforms. Compared to bank finance, platform finance increases sellers' threshold quantities without stockouts in each channel, encouraging higher quantities in both channels. The study explores the channel substitution effect on sellers' quantity decisions, offering insights for optimal financing and channel structures to boost profits.

2 - Stackelberg game approaches for the adoption of blockchain technology in competitive supply chains considering traceability awareness of consumers

Zijing Yang, Songsong Liu

This work aims to investigate the blockchain introduction strategies and conditions in a competitive supply chain considering traceability awareness of consumers and the cost of blockchain technology base on game theory. In addition, this work explores supply chain fair coordination issues on the key supply chain decisions for adopting blockchain technology through a cost sharing contract. Firstly, through a proposed Stackelberg game model, a supply chain with two competitive suppliers, one manufacturer and one retailer is investigated under two scenarios, including decision-making without blockchain technology, with blockchain technology. Next, to explore the fair coordination of blockchain technology, the Nash bargaining method is adopted. Theoretical analysis and computational simulation are conducted to show how prices and profits are influenced by traceability awareness of consumers and competitive intensity of suppliers, and the impact of blockchain costs towards blockchain introduction. The results imply that the cost of adopting traceability technology is an important factor to be considered when supply chains adopt the technology. Firstly, this work enriches the literature by extending the relevant theory to considering the traceability awareness of consumers, as well as the cost of adoption the blockchain technology. Secondly, by considering cost sharing coordination, our research contributes to cooperation and fairness among supply chain members.

3 - Branch-and-price with novel cuts, and a new Stackelberg Security Game

Pamela Alejandra Bustamante Faúndez

Anticipating the strategies of potential attackers is crucial for protecting critical infrastructure. We can represent the challenge of the defenders of such infrastructure as a Stackelberg security game. The defender must decide how to allocate limited resources to protect specific targets, aiming to maximize their expected utility (such as minimizing the extent of damage) and considering that attackers will respond in a way that is most advantageous to them.

We present novel and stronger valid inequalities to find a Strong Stackelberg Equilibrium in both Stackelberg games and Stackelberg security games. We also present a new Stackelberg security game that aims to protect targets with a defined budget. We use branch-and-price in this new game to show that our approach outperforms the standard formulation in the literature, and we conduct an extensive computational study to analyze the impact of various branch-and-price parameters on the performance of our method in different game settings.

expected to result in computational efficiencies; however, some information loss should also be expected since the nondominated set will no longer be computed exactly. With the goal of devising methods that lead to minimal information loss, we investigate two alternative approaches: one suggests eliminating objectives, the other combining them. The elimination method uses the similarity between an objective function's gradient and its projection onto objects defined by the remaining objectives. The combination approach relies on clustering the objective function gradients. We assess the effectiveness of the approaches on library problem instances. We report quality measures such as the coverage error, additive epsilon indicator and hypervolume to evaluate the representations obtained by solving the reduced problems. Preliminary findings indicate that proposed reductions may be effective ways to obtain quick representations of the original problem.

2 - Parallel computation of the Pareto frontier for the bi-objective minimum spanning tree problem

Mariagrazia Cairo, Lavinia Amorosi, Dell'Olmo Paolo

This talk presents a parallel algorithm for the bi-objective minimum spanning tree (BMST) problem which takes advantage of a two-phase procedure for the generation of a complete set of efficient solutions. The first phase involves computing the extreme supported efficient solutions by resorting to an algorithmic approach (Prim embedded in a dichotomic search), while the second phase focuses on determining the non-extreme supported and non-supported efficient solutions. In this latter phase, all spanning trees of a connected graph are generated through edge interchanges based on increasing evaluation of reduced costs of associated weighted linear programs. The results of preliminary computational experiments will be discussed.

3 - On the accurate detection of the Pareto frontier for bi-objective mixed integer linear problems

Lavinia Amorosi, Marianna De Santis

In this talk, we focus on bi-objective mixed integer linear programming problems (BOMILPs). Due to their structure, the detection of their Pareto frontier can be hard to compute from an accuracy perspective. We propose a new criterion space algorithm able to deal with this difficulty, detecting the exact non dominated set of a BOMILP. The algorithm alternates the resolution of single objective mixed integer linear problems and bi-objective linear problems. During its execution a filtering procedure, based on a tree data-structure called BoT (bi-objective tree), stores in ordered manner all non-dominated points and segments found. The performance of the algorithm is further improved by the use of suitably defined cuts. Experimental results on a testbed of instances and a comparison with an existing algorithm will be presented.

4 - Last-Mile Logistics: Comparing Alternative Formulations of a Bi-Objective Vehicle Routing Problem Based on K-Sum Minimization

Filippo Ranza, Renata Mansini, Justo Puerto, Roberto Zanotti

In this work, we introduce a bi-objective Vehicle Routing Problem that minimizes both the routing cost and the impact on citizens evaluated in terms of pollution, noise, and safety (social impact). To measure the latter we consider the number of traversals multiplied by the population living on each street. Formulated on a multi-graph, the problem considers different paths between each pair of nodes. The two objective functions are solved lexicographically. First, the routing cost is minimized, then the social impact is optimized by allowing a predefined degradation of the routing cost. Several K-Sum compact formulations as described in [1] and [2] in addition to a non compact one are tested and compared. A comprehensive sensitivity analysis is also conducted on multiple realistic instances, considering different k values. References [1] Ogryczak, Włodzimierz, and Arie Tamir. 1 - The sphere packing problem on Tori

Andreas Spomer

How can we arrange spheres in a way such that they fill out as much space as possible? This age-old mathematical question has a lot of applications, not only in mathematics, but also in physics and other areas of natural science. The problem has been studied in many interesting spaces, for example in finite fields, on the sphere and in the Euclidean space. In recent times, a lot of progress has been made, for example by the winner of the Fields medal Maryna Viazovska, who solved the problem in the eight dimensional Euclidean space. In my talk, I want to consider this problem on spaces that are given by the Cartesian product of spheres. We will look at a family of dense packings and discuss how to verify their optimality using semidefinite programming, harmonic analysis and sum-of-squares techniques. Furthermore, we will relate this problem to other packing problems in different spaces.

2 - From approximate to exact optimal solutions of large semidefinite programs

David de Laat, Henry Cohn, Nando Leijenhorst

For semidefinite programs where the solution is nonunique but the dimension of the optimal face is smaller than the dimension of the affine space, it is not immediately clear how to round the numerical output of an interior-point solver to an exact optimal solution. Rounding each entry of the solution matrices often does not work since the analytical center of the optimal face is complicated to describe. Projecting into the affine space also does not work, since the projection will not be positive semidefinite. In [Dostert, de Laat, Moustrou 2021] a rounding approach using the LLL algorithm is given. I will explain our improved method, using the LLL algorithm in different ways, which is much faster for large semidefinite programs. This allows us to prove the optimality of several spherical codes using semidefinite programming bounds.

3 - Exploiting symmetries in optimal quantum circuit design

Frank de Meijer, Dion Gijswijt, Renata Sotirov

A physical limitation in quantum circuit design is the fact that gates in a quantum system can only act on qubits that are physically adjacent in the architecture. To overcome this problem, SWAP gates need to be inserted to make the circuit physically realizable. The nearest neighbor compliance problem (NNCP) asks for an optimal embedding of qubits in a given architecture such that the total number of SWAP gates to be inserted is minimized. In this paper we study the NNCP on general quantum architectures. Building upon an existing LP formulation, we show how the model can be reduced by exploiting the symmetries of the graph underlying the formulation. The resulting model is equivalent to a generalized network flow problem and follows from an analysis of the automorphism group of Cayley graphs generated by transpositions. As a byproduct of our approach, we show that the NNCP is polynomial time solvable for several classes of symmetric quantum architectures. Numerical tests on various architectures indicate that the reduction in the number of variables and constraints is on average at least 90%. This opens the way to solving NNCP instances on large quantum circuits that are far beyond the computational capacity when solving them without the exploitation of symmetries.

Stochastic Models in Service Operations II

Stream: Stochastic Modelling

Invited session

Chair: Roshan Mahes

Chair: Roshan Mahes

1 - Performance analysis of a cluster-based service system

Sabine Wittevrongel, Osama Salameh

Cluster-based service systems are used to provide parallel processing of jobs. A specific feature of such systems is that jobs are divided into tasks that should run in parallel on different servers. A job does not start execution unless the required number of idle servers is available. This paper proposes a new analytical model based on Markov chain theory that captures the typical dynamics of such cluster-based system with finite buffer size. Through our analysis, key performance measures of a cluster-based service system such as the job blocking probability, the average job delay in the queue or the average utilization of the cluster servers can be estimated. The application of the model to cloud centers with thousands of servers and a heterogeneous workload is shown possible.

2 - Completion Times of Jobs on Two-State Service Processes and Their Asymptotic Behavior

Melike Baykal-Gursoy

We consider a repairable service system in which a server experiences randomly occurring service interruptions during which the server works slowly. Every service-state change preempts the task that is being processed. The server may then replace the task with a different one, or it may repeat the same task from the beginning, under the new service-state. We study the completion time of a task under the last two cases as a function of the task size distribution, the service interruption frequency/severity, and the repair frequency. We derive closed form expressions for the completion time distribution in Laplace domain under replace and repeat recovery disciplines and present their asymptotic behavior. In general, the heavy tailed behavior of completion times arises due to the heavy tailness of the task time. However, in the preempt-repeat service discipline, even in the case that the server still serves during interruptions albeit at a slower rate, completion times may demonstrate power tail behavior for exponential tail task time distributions. Furthermore, our results reveal that the stationary first order moments, i.e., expected completion time, expected number in the system in infinite server queues with Markov modulated service processes are insensitive to the way the service modulation affects the servers, system-wide modulation affecting every server simultaneously vs identical modulation affecting each server independently.

3 - Appointment Scheduling with Updates: An Exact and Optimal Approach

Roshan Mahes, Alex Kuiper

Traditionally, appointment schedules have been determined by minimizing a specific cost function consisting of clients' waiting times and server idling. Under stochastic service times, this intra-day problem is predominantly studied in a static sense, assuming a fixed schedule. However, technological advancements have opened up the possibility of communicating with clients during the day. Using such channels allows for updating appointment schedules on the fly, for example, by postponing appointments in case of overcrowding. Yet, while its promise is clear, sending updates at the wrong moments, or too many, may be ineffective or unrealistic, potentially causing client confusion and frustration. Therefore, the static appointment scheduling problem is extended to a dynamic setting that allows the rescheduling of future clients.

Three rescheduling paradigms - via arrivals, the timeline, or the waiting room - are introduced that can be solved to optimality via dynamic programming. By rescheduling, the scheduler takes control over the

running session, and the experiments indicate that total costs are significantly decreasing, even with relatively few updates. The benefits concentrate on increasing utilization (less idling). The magnitude of the decrease is moderated by the length of the grace period, which accounts for not sending updates to clients possibly underway. Also, we argue that the third paradigm is most effective for rescheduling.

1 - A Variational Formulation for a Trust and Reputation System

Attilio Marciànò, Gabriella Colajanni, Patrizia Daniele, Sofia Giuffrè

Trust and reputation systems play a pivotal role in modern decentralized environments, fostering cooperation and mitigating risks in various online interactions. The aim of our work is to introduce a variational formulation approach to model and analyze trust and reputation systems. By formulating trust and reputation as variational problems, this approach offers a novel perspective on understanding the underlying mechanisms governing trust establishment. The variational formulation provides a mathematical framework to determine the equilibrium weighted trust values, taking into account that each trustee tries to maximize its gain, namely the utility minus the costs. We illustrate the applicability of this variational formulation through a plethora of simulations, demonstrating its effectiveness in modeling trust and reputation systems. Insights gained from this approach offer valuable guidance for the design and implementation of more reliable and efficient trust and reputation mechanism in decentralized environments.

2 - From many sources to many users: water allocation mechanisms under resource dynamics

Petros Xepapadeas

We study optimal water management of many sources which are partitioned into surface and groundwater, with water transportation through natural processes being possible among water bodies. Water stock dynamics involve natural inflows and outflows from water users' abstractions as well as natural processes. Sustainability constraints are introduced by applying terminal conditions on the water stocks. The net benefits of the users are quadratic with concave gross benefits and convex costs based on the amount of water used from each water source. We focus on developing two sequential water abstraction solutions based on serial dictatorship under explicit resource dynamic constraints. The first is when each sequential user commits to a path for the whole planning horizon, and the second is when the serial dictatorship water abstraction decisions are completed in each time period. Simultaneous water management is also studied in terms of cooperative solutions and non-cooperative open-loop and feedback Nash equilibrium solutions. The sequential and simultaneous solutions are then compared in terms of aggregate and individual benefits, and in terms of meeting the sustainability constraints. The results of the comparison are used to characterize water management policies.

3 - Enhancing Parcel Pickup and Delivery Services with UAV Integration

Gabriella Colajanni, Patrizia Daniele, Francesco Schillaci

The optimization of parcel pickup and delivery services aims to enhance efficiency, reliability, and cost-effectiveness across the logistics process, encompassing route optimization, delivery time reduction, and cost minimization. This study delves into optimizing parcel services by integrating Unmanned Aerial Vehicles (UAVs), commonly referred to as drones, into logistics operations, with a specific

focus on the last-mile delivery segment. The research endeavors to bolster the efficiency, dependability, and cost-efficiency of the entire delivery chain. We examine a hybrid hierarchical system that amalgamates drones with conventional delivery methods to efficiently transport parcels from their origin points to final destinations, thereby curbing costs and enhancing delivery timelines. The study presents a constrained optimization problem along with its variational formulation. Numerical simulations underscore how the incorporation of drones into multi-layered parcel delivery networks offers a promising avenue to elevate the efficiency, velocity, and adaptability of parcel delivery systems. This innovative approach empowers companies to overcome logistical hurdles, extend their operational footprint to remote areas, substantially diminish environmental emissions, and refine delivery timelines, particularly for last-mile deliveries.

4 - A Multi-Leader-Follower Game for the Analysis of the Interactions in Donation-Based Live-Streaming Platforms

Laura Rosa Maria Scrimali

This paper examines the interactions between content creators and viewers in donation-based live-streaming platforms. Specifically, creators produce their content, then viewers enjoy the live-streaming and decide to donate money to creators. To capture the sequential decision process of the model, we introduce a multi-leader-follower game, in which creators act as the leaders of the game and viewers as the followers. Creators first optimize their performance level and the duration of the streams to maximize their profit. Then, viewers optimize the time spent watching a live stream to maximize their utility. Thus, the first stage of the game models the non-cooperative competition among creators, while the second stage represents the behaviour of viewers deciding on their content demands. We formulate these stages as Nash equilibrium problems, and then as variational inequalities. We analyze the existence and uniqueness of the Stackelberg equilibrium. Then, we derive a supervised learning algorithm to estimate the parameters of the associated artificial neural network model, focusing on the advertisement function, to test our achievements.

1 - Sparse convex nonparametric least squares via convex optimization

Zhiqiang Liao

We study the problem of variable selection in convex nonparametric least squares. Whereas the Lasso is a popular technique for simultaneous estimation and variable selection, its performance is unknown in convex regression problems. In this work, we investigate the performance of the Lasso regularized convex nonparametric least squares estimator in a high-dimensional setting and propose an alternative approach based on the unique structure of the subgradients. Our proposed estimators perform favorably, while generally leading to sparser models, relative to the other predictive models via the standard Lasso. Further, our estimators can be expressed as solutions to convex optimization problems and are amenable to modern optimization algorithms.

2 - A global optimization method for a quadratic reverse convex programming problem

Syuuji Yamada

In this talk, we propose a global optimization method for a quadratic reverse convex programming problem (QRC) whose feasible set is expressed as the area excluded the interior of a convex set from another convex set. It is known that many global optimization problems can be transformed into such a problem. Iterative solution methods for solving (QRC) have been proposed by many other researchers. One of the difficulty for solving (QRC) is that all locally optimal solutions do not always satisfy KKT conditions. In order to overcome this drawback, we introduce a procedure by combining parametric optimization techniques and Lipschitz optimization methods for finding locally optimal solutions of (QRC). Moreover, we propose an algorithm for finding a globally optimal solution of (QRC) by incorporating such a procedure into a branch and bound procedure.

3 - Non-Euclidean Gradient Methods for matrix completion

Susan Ghaderi, Yves Moreau, Masoud Ahooshoh

This study develops and analyzes non-Euclidean gradient methods for minimizing relatively smooth nonconvex functions using Bregman distances. We explore both constant and dynamic step-size strategies, examining their convergence and complexity, particularly under relative strong convexity. We demonstrate the methods' effectiveness in matrix factorization, matrix completion, and image inpainting on real datasets, validating our theoretical findings.

4 - Adaptive linesearch-free proximal gradient methods under Hölder gradient continuity

Puya Latafat, Konstantinos Oikonomidis, Emanuel Laude, Andreas Themelis, Panagiotis Patrinos

This work studies a class of adaptive methods for structured convex optimization that use large stepsizes on par with linesearch methods without employing any backtracking procedure. We show that the convergence of such methods extends beyond Lipschitzian setting and encompasses the case of local Hölder gradient continuity. Unlike conventional approaches that often resort to epsilon-oracles or linesearch procedures to address the absence of local Lipschitz continuity, we leverage plain Hölder inequalities without approximation or linesearch. Our analysis establishes exact convergence results without the need for prior knowledge of local Hölder constants or the order of Hölder continuity.

Chair: *José Vicente-Pérez*

Chair: *José Vicente-Pérez*

1 - On the strong Slater condition of linear systems with an evenly convex constraint set

Margarita Rodríguez Álvarez, José Vicente-Pérez

The strong Slater condition plays a significant role in the stability analysis of linear semi-infinite inequality systems. In this work, we deal with the stability of the intersection of a given evenly convex set with the solution set of a linear system whose coefficients can be arbitrarily perturbed. More specifically, we analyze the set of strong Slater points associated to a given linear inequality system with an evenly convex constraint set X . Such sets become the solution sets of linear systems containing weak inequalities, strict inequalities and strong Slater type inequalities. For this type of systems we characterize the existence of solutions by means of dual conditions in terms of the system data, extending some results given by other authors in the field of stability of semi-infinite linear systems with solutions in a certain closed convex set.

2 - C-conjugacy for set-valued functions and first results on duality theory

Maria Dolores Fajardo

In this talk we deal with set-valued functions with values in the power set of a separated locally convex space where a nontrivial pointed cone induces a partial order relation. We present a conjugation pattern which allows a biconjugation theorem when the set-valued function is proper and evenly convex, which means that its epigraph is the intersection of an arbitrary family of open half-spaces. Duality theory is then developed via perturbational approach and the first results are also presented.

3 - On Fenchel c-conjugate dual problems for DC optimization

Jose Vidal-Nunez, Maria Dolores Fajardo

In this talk we present two Fenchel-type dual problems for a DC (difference of convex functions) optimization primal problem. These dual problems are built by means of the c-conjugation scheme, a pattern of conjugation which has been shown to be suitable for evenly convex functions. In particular, we study characterizations of weak, strong and stable strong duality for both pairs of primal-dual problems. Finally, we also give conditions which relate the existence of strong and stable strong duality for both pairs.

4 - A review on the radius of robust feasibility of uncertain mathematical programs

José Vicente-Pérez, Miguel Goberna, V. Jeyakumar, Guoyin Li

The radius of robust feasibility provides a numerical value for the largest possible uncertainty set that guarantees feasibility of a robust counterpart of a mathematical program with uncertain constraints. The objective of this review of the state-of-the-art in this field is to present this useful tool of robust optimization to its potential users and to avoid undesirable overlapping of research works on the topic as those we have recently detected. In this paper we overview the existing literature on the radius of robust feasibility in continuous and mixed-integer linearly constrained programs, linearly constrained semi-infinite programs, convexly constrained programs, and conic linearly constrained programs. We also analyze the connection between the radius of robust feasibility and the distance to ill-posedness for different types of uncertain mathematical programs.

1 - Rewarding Primary Dealer Performance

Aleksandrs Smilgins, Sasa Pecek, Jens Leth Hougaard, Peter Bogetoft

We study the problem of allocating compensation for a collective effort of competing market participants, such as rewarding market-makers tasked to maintain active price quotations and low bid-ask spreads. Several countries regularly issue government bonds, typically via an auction, and the secondary market stability is important for success of future auctions. In order to achieve that, participation in auctions is restricted to selected bidders who are in turn required to be active in the secondary market. Furthermore, some debt management offices provide annual monetary compensation to incentivize the secondary market performance. We develop a framework to design optimal allocation of the annual incentive amount for individual secondary market performance over time and multiple markets. The proposed scheme is compared to the one currently used by the Danish Debt Management Office.

2 - EPIC Fail: How Below-Bid Pricing Backfires in Multiunit Auctions

Daniel Marszalec, Alexander Teytelboym, Sanna Laksá

Auctions with below-bid pricing (e.g., uniform-price, and ascending auctions) have remarkable theoretical properties, but practitioners are skeptical about their implementation. We present a dynamic model of collusion in multiunit auctions that explains this gap between theory and practice. To sustain collusion at the reserve price, bidders submit crank-handle bids. The cost of sustaining crank-handle collusion depends on the degree of below-bid pricing in the auction. Our model predicts that crank-handle collusion is easier to sustain in auctions with more below-bid pricing and when bidders are more symmetric. Evidence from auctions of fishing quota in the Faroe Islands supports our predictions.

3 - Fair integer programming under dichotomous preferences

Tom Demeulemeester, Dries Goossens, Ben Hermans, Roel Lens

One cannot make truly fair decisions using integer linear programs unless one controls the selection probabilities of the (possibly many) optimal solutions. For this purpose, we propose a unified framework when binary decision variables represent agents with dichotomous preferences, who only care about whether they are selected in the final solution. We develop several general-purpose algorithms to fairly select optimal solutions, for example, by maximizing the Nash product or the minimum selection probability, or by using a random ordering of the agents as a selection criterion (Random Serial Dictatorship). We also discuss in detail how to extend the proposed methods when agents have cardinal preferences. As such, we embed the "black-box" procedure of solving an integer linear program into a framework that is explainable from start to finish. Lastly, we evaluate the proposed methods on two specific applications, namely kidney exchange (dichotomous preferences) and the scheduling problem of minimizing total tardiness on a single machine (cardinal preferences). We find that while the methods maximizing the Nash product or the minimum selection probability outperform the other methods on the evaluated welfare criteria, methods such as Random Serial Dictatorship perform reasonably well in computation times that are similar to those of finding a single optimal solution.

4 - Stable Matching with Contingent Priorities

Ignacio Rios

We study stable matching problems under contingent priorities, whereby the clearinghouse prioritizes some agents based on the allocation of others. Using school choice as a motivating example, we first introduce a stylized model of a many-to-one matching market where the clearinghouse aims to prioritize applicants with siblings assigned to the same school and match them together. We provide a series of guidelines to implement these contingent priorities and introduce two novel concepts of stability that account for them. We study some properties of the corresponding mechanisms, including the existence of a stable assignment under contingent priorities, its incentive properties, and the complexity of finding one if it exists. Moreover, we provide mathematical programming formulations to find such stable assignments whenever they exist. Finally, using data from the Chilean school choice system, we show that our framework can significantly increase the number of siblings assigned together while having no large effect on students without siblings.

Chair: *Konrad Kulakowski*

1 - Enhancing Sustainable Procurement in the UAE's Public Sector: An AHP Framework for Minimizing Carbon Emissions

Alia Alkaabi

Amidst rapid industrial growth, the UAE's public sector plays a crucial role in national infrastructure. Traditional procurement practices in this sector have primarily focused on commercial and technical criteria, with far less emphasis on environmental sustainability. This reliance on carbon-intensive goods and services has markedly increased the sector's carbon footprint. This research uses the Analytic Hierarchy Process (AHP) to improve sustainable procurement decisions, aiming to substantially reduce carbon emissions within the UAE's public sector. By integrating a comprehensive set of criteria—environmental, economic, social, and technical—the study develops a detailed AHP framework to systematically evaluate and select procurement options that support sustainability objectives. The findings prioritize procurement practices that significantly reduce the sector's carbon footprint, thus aligning procurement strategies with the UAE's broader sustainability goals.

2 - Interval Pairwise Comparisons in the Presence of Infeasibilities: A Review and Numerical Experiments

Jiri Mazurek, Bruce Golden, Jiaqi Wang

Pairwise comparisons constitute a fundamental part of many multiple-criteria decision-making methods designed to solve complex real-world problems. One of the pervasive features associated with any problems' complexity is uncertainty. Experts are rarely able to consistently and accurately evaluate a set of alternatives under consideration due to time pressure, cognitive bias, the intricacy or intangible essence of the problem, a lack of requisite knowledge or experience, or other reasons. Interval pairwise comparisons (IPCs) allow for this uncertainty in a natural way; however, the problem of inconsistency (or infeasibility) may arise. That is, a set of interval comparisons may not allow experts to find a solution in the form of a priority vector. The aim of this paper is to provide a review of existing literature on this topic and to compare existing methods via numerical examples and simulations which indicate that the Interval Stretching Method is superior to other published methods. In addition, the problem of solution uniqueness is investigated for selected methods. Last but not least, a new theoretical framework for the evaluation of the extent of the modification of an original IPC matrix is provided as well.

3 - A Desktop Tool for Multicriteria Decision Analysis

Radomir Perzina

There exists wide range of software products to support decision making. However, the main disadvantage of these products is their commercial nature, which makes them relatively expensive and inaccessible to small companies, students, and researchers. Addressing this gap, we introduce a novel desktop tool called Multicriteria Decision Assistant (MDA). MDA emerges as an evolution of a previous software, the FDA, enhancing user experience by eliminating the need for an internet connection, thus addressing privacy and data security concerns by preventing sensitive data from being sent to external servers. This feature significantly increases the tool's appeal to users wary of data privacy issues. What sets the tool apart is not just its cost-free accessibility but its educational potential. Unlike many decision support tools that operate as black boxes, MDA makes the decision-making process transparent, displaying the results of intermediate calculations. This transparency is invaluable for educational purposes, allowing students to grasp the underlying principles of multicriteria decision-making and encouraging a deeper understanding of the decision process itself. The proposed software package is demonstrated on an illustrating example of a real-life decision problem.

4 - Forward Accuracy in AHP/ANP: Unraveling the Consistency-Compatibility Conundrum through Color Brightness Comparisons

Adriana Miclea

This paper examines the existence of a linear relationship between the consistency ratio and the compatibility index in the AHP/ANP framework. The linear relationship is tested with respect to accuracy principle, using an original development referred as "forward accuracy". For several years, students in Bucharest University of Economic Studies were asked to pairwise compare the brightness of five colors. Their consistency and compatibility indices were collected and based on these, accuracy curves among these two measures were inferred. While there is hope in the AHP/ANP methodology that a low value of the inconsistency ratio will grant compatibility and the rightness of the decision-making structures, there is rather an insignificant number of practical experiments to challenge this one. This multi-annual experiment shows that in the simple situation when brightness is compared, accuracy curves as linear relationships between consistency and compatibility remain similar, while on the same accuracy curve one could find high consistency with low compatibility and the other way around. Conclusions are two-folded: is need to perform lots of experiments, to figure out what is the acceptable threshold of inconsistency ratio and alternative measures like "forward accuracy" where the impact of a pair (consistency-compatibility) on the shape of the linear relationship is assessed in terms of future impact could prove useful.

1 - Sustainable Dynamic Routing Framework for Efficient E-Grocery Delivery

Valentas Gruzauskas, Aurelija Burinskiene

In urban settings, e-grocery delivery significantly impacts energy use and air pollution. Traditional routing solutions, while addressing general transportation, fall short in the specific area of fresh food delivery, which demands a focus on sustainability. Our research introduces a dynamic route planning framework that integrates graph neural networks for traffic flow forecasting with traditional optimization techniques. This framework is designed to balance environmental impact, food quality, and operational costs, adapting to changing urban logistics factors such as food demand, fleet size, and traffic conditions. The framework also incorporates advanced information-sharing strategies, enhancing its adaptability and efficiency in real-time scenarios. We emphasize the importance of sustainable and resilient solutions in the context of urban e-grocery logistics. The proposed solution, scalable for large-scale agent-based modeling, aims to establish more resilient and sustainable urban delivery systems, with a future focus on a specific city case study to demonstrate its practical effectiveness. The novelty in our approach is the inclusion of real-time information-sharing strategies and a focus on sustainability and resilience in route scheduling, which sets it apart from traditional systems. This fusion of advanced predictive analytics with practical optimization offers a new pathway to tackle the environmental and logistical challenges of urban e-grocery delivery.

2 - Integrating and evaluating value-oriented decision making mechanisms into inventory policies

Philipp Erfurth, Matthias Gerhard Wichmann

In multi-period inventory management, decisions are made about the timing and quantity of purchases, as well as inventory control of the goods. To minimize costs, inventory policies are used for the procurement of goods. Most policies assume constant purchase prices and stochastic demand. However, products and services are often subject to price fluctuations. This raises three challenges: (1) the economic advantage of inventory policies when purchase prices fluctuate, (2) the integration of value-oriented decision mechanisms into inventory policies, and (3) their comparison. To address these issues, a simulation study on inventory policies was conducted taking value orientation and fluctuating purchase prices into account. The study focuses on developing, integrating, and evaluating value-oriented inventory policies for goods with fluctuating prices. It compares their performance with conventional inventory policies. The results suggest that integrating value-oriented decision mechanisms can yield benefits even with minor price fluctuations in the market. As price fluctuations increase and solution robustness becomes more important, the need to integrate value-oriented decision mechanisms into inventory policies remains. The results indicate that value-oriented inventory policies can leverage cost potential by up to 20%. Therefore, further research is needed to efficiently configure these policies for the economical procurement and storage of goods during price fluctuations.

3 - Optimizing Job Offer Packages: How Can Organizations Enhance Personnel Selection?

Saeed Najafi-Zangeneh, Naser Shams, Olivier Gossner, Ehsan Abbasi

Personnel selection in competitive two-sided markets presents challenges for organizations seeking to attract high-quality candidates while managing costs. However, existing models often overlook the optimization of job-offer packages to address both candidate preferences and organizational objectives. This paper addresses this research gap by proposing a novel mathematical model for determining the optimal job offer package. Our model integrates candidate preferences and organizational costs, offering a comprehensive solution to the selection process. Utilizing a two-stage Mixed-Integer Linear Programming (MILP) approach, we employ the Gale and Shapley algorithm to facilitate efficient matching. Through a small case study, we validate the effectiveness of our model in providing actionable insights for organizations seeking to enhance their hiring processes and attract top talent.

4 - Product bundling strategy for co-live streaming E-commerce considering consumer subscription

Cai Shoujie

Livestreaming e-commerce has emerged as a highly effective channel for manufacturers and retailers recently. When two streamers from different rooms collaborate to host a co-live streaming event and individually promote products in their respective rooms, it attracts various types of consumers with assessments to products. In this background, we explore the optimal decisions and the best sales strategy for three common livestreaming sales strategies: pure component (PC), mixed bundling (MB), and pure bundling (PB). The study shows that it is more advantageous for streamers of similar or identical types to collaborate in a co-live streaming event, and MB and PB strategies consistently outperform PC strategy; however, a co-live streaming event doesn't offer significant advantages over a solo-live one when there is already sufficient traffic. The extended studies explore the robustness of the findings and uncover two additional insights. Firstly, a co-live streaming room with a higher proportion of co-subscribers yields more profits. Secondly, if two streamers sell similar or identical products, PB strategy is more effective if valuation discounts are low, whereas MB strategy shines. However, when co-live streaming sells significant different products, MB strategy is advantageous only when streamers with lower traffic recommend higher value products.

Not The Excellence In Practice Award

Stream: Making an Impact

Invited session

Chair: Ruth Kaufman

1 - Not The Excellence In Practice Award

Making An Impact, L. Alberto Franco, Karsten Kieckhäfer, Gilberto Montibeller, Louis Bouvier, Trung Hieu Tran, El Mehdi Er Raqabi

The aim of this 90' session is to explore the aspects of practice that do not get included in the materials submitted for awards such as the EURO Excellence in Practice Award. Submissions naturally focus on the criteria being judged: the originality of the methodology, the scientific excellence, the impact, and so on. But anybody who has been engaged in a practical application will know that this only tells part of the story. To get to the stage of an implemented application, there will have been many hurdles along the way: getting all the data, making sure it is correct, convincing all the stakeholders, overcoming fears and doubts of the people who have to change their way of working, and so forth. In this session, we will invite panellists to give a short presentation of these aspects of their projects, consider how they dealt with the challenges and identify key lessons, to be followed by questions and discussion with the audience on the key issues and how we address them. The latest details of panel members can be found on the Making an Impact page on the main conference website (euro2024cph.dk/programme/making-an-impact-2024)

Fuzzy sets and systems

Stream: Multiple Criteria Decision Analysis

Invited session

Chair: Gia Sirbiladze

1 - Associated Probabilities and Insufficient Expert Data in Multi-Criteria Decision Making

Tinatin Davitashvili, Gia Sirbiladze

Problems of modeling of uncertainty and imprecision for the analysis of the insufficient expert data (IED) is considered in the environment of interactive group multi-criteria decision making (MCDM). Uncertainty index is presented by the fuzzy measure on alternatives set. Based on the informational entropy maximum principle, moments' method for the IED is developed for the evaluation of associated probabilities class (APC) of Choquet's second order capacity. The second pole of the IED - the data imprecision in the form of a fuzzy subset (image) on alternatives set is constructed. Based on the Sugeno finite integral most typical value (MTV) as a prediction on possible alternatives set for the IED is constructed. In MTV the both poles of the IED (APC and image) are accumulated. The numerical example illustrates the possibilities of the approach, in the optimal selection of recommendation elements from MCDM alternatives. The sensitive and comparative analysis for this example is provided.

2 - Humanitarian Relief Logistics Fuzzy Planning Model for the Shelters' Location and Victims' Evacuation in the Disaster Zone

Gia Sirbiladze

We assume fuzziness in emergency logistic planning models for the disaster zone, such as the covering, location, transportation and routing problems. We consider a fuzzy multi-objective emergency shelters location and victims evacuation problem (FMOESLVEP) in the disaster-stricken zone. The model objectives include (1) maximizing the total selection reliability index of opened shelters; (2) minimizing total costs, including fixed costs for opening shelters, victim transportation costs, and service costs, (3) minimizing of monotone expectation of total time for victims' evacuation, and (4) minimizing the number of open shelters. FMOESLVEP models are developed for the different input fuzzy information. For the evaluation of selection reliability indexes of opened shelters the models take into account the interactions between decision making attributes by aggregating the extended Choquet integral. The realization scheme of the solution for the FMOESLVEP models is given.

3 - Facility Location Selection Problem based on Picture Fuzzy TOPSIS

Irina Khutsishvili, Gia Sirbiladze

In the present research, a decision support methodology for facility location selection problems is developed. The methodology is based on the TOPSIS (Technique for Order Performance by Similarity to Ideal Solution) approach under a picture fuzzy environment. We are focusing on a special case of facility location problem, namely location planning for service centers. A set of potential center sites, or alternatives, are typically involved in this kind of challenge, and they are assessed based on some weighted criteria. The alternative that best meets each criterion will be selected for implementation. To evaluate criteria our approach uses experts' assessments, that is in the proposed methodology the values of the criteria are expressed in picture fuzzy numbers, given by the group of experts. The case when the information on the criteria weights is completely unknown is considered. In the context of picture fuzzy sets, the criteria weights identification based on De Luca-Termini information entropy is presented. Hence, the proposed approach is based on a picture fuzzy TOPSIS decision-making model with entropy weights. The fuzzy positive-ideal solution (FPIS) and fuzzy negative-ideal solution (FNIS) are first defined using the TOPSIS algorithm. Then the ranking of alternatives is performed following the proximity of their distances to both FPIS and FNIS. For this purpose, the picture weighted Hamming distance is used.

4 - Evidence Theory and Fuzzy Discriminations in MCDM. Application in Emergency Psychiatric Diagnostics

Bezhan Ghvaberidze, Gia Sirbiladze

Today, much attention is paid to the engineering of dependable and resilient intelligent systems and models. This direction includes multi-criteria decision making (MCDM) models and systems in emergency situations. A new interactive MCDM approach based on evidence theory and fuzzy discrimination analysis is developed. MCDM's utilities in the discrimination q-rung orthopair fuzzy values in the Dempster-Shaper's believe structure environment are transformed. New aggregation operators - extensions of Dempster's extremal expectations under discrimination q-rung orthopair fuzzy information are constructed. MCDM's alternatives by new constructed operators are ranked. For the illustration of obtained results a numerical example is created from Emergency Psychiatric Diagnostics.

DEA applications in Policy Making and Planning II

Stream: Data Envelopment Analysis and its Application

Invited session

Chair: Thyago Nepomuceno

1 - Measuring efficiency in tourism: a problem of shared factors and multiple attributes in DEA

Sonia Avilés-Sacoto, Estefanía Avilés-Sacoto, Wade Cook, David Güemes-Castorena

This paper examines the tourism industry in Mexico, focusing specifically on the performance of each of its 32 states. To facilitate the development of an appropriate performance measurement tool, we begin with the data envelopment analysis (DEA) methodology, an optimization tool used for evaluating the efficiencies of a set of decision-making units (DMUs). While it is usually assumed that each DMU functions independently of other units, having its own set of inputs and outputs, there are situations where the DMUs can be interdependent due to the presence of shared factors. Thus, a DMU can share an input or output with other DMUs, thereby generating sub-groups of DMUs. In such a setting, like the one considered herein, one must view a projection to the frontier as involving all sub-group members simultaneously. As well, in some cases the shared factor cannot be split up and assigned to each sub-group member separately. This situation can become even more complex in a two-stage setting where a DMU can share a factor with some other DMUs and the DMU groupings are different in one stage than in another. Finally, in the study herein we consider the presence of different attributes, i.e. different types of tourism.

2 - Incorporating the Benefit of the Doubt Indicator for Improved Electric Power Management

Lucio Camara e Silva, Cristiane Perla Castro e Sant'Anna, Josenildo Ferreira, Aldsmtyhys Cruz, Thyago Nepomuceno

This study introduces a composite indicator based on the Benefit of the Doubt (BoD) to support System Operation Centers in adjusting real-time schedules to meet demands of Electric Power Systems (EPS). It addresses the challenge of selecting power plants for increased electricity generation in northeastern Brazil, undertaken by a company within the Brazilian electricity sector established in 1998. This entity is tasked with coordinating and overseeing the operation of generation and transmission facilities within the National Interconnected System. The evaluation focuses on the Northeast Requirement Load (NRL), with output indicators including operating time, response time, energy potential, and variable costs. Decision-makers analyze the results and concur with the prioritization of alternatives, employing the model to facilitate the selection of viable Thermoelectric Power Plants to alleviate the generation shortfall in northeast Brazil over a specified timeframe.

3 - Improving the Efficiency of Criminal Investigations with a Multi-needs Approach for Case Reassignments

Thyago Nepomuceno, Akram Dehnokhalaji, Erik Alda, Miguel Gustavo Gomes da Silva

By assuming a proportional alteration in the output/input ratio, DEA can estimate the additional resources necessary for police units in anticipation of criminal activities. However, reallocating human resources and capital poses significant challenges within public administrations, often influenced more by political considerations than technical merits.

This study proposes a novel approach that integrates non-parametric frontier estimations with a prioritization reasoning to guide the redistribution of cases, rather than personnel, within law enforcement agencies. We assess the production capacity of police units utilizing Data Envelopment Analysis. A multicriteria framework is incorporated to facilitate reassigning criminal cases from police stations working at full capacity to units with available resources. This approach provides an efficient and fair allocation of cases, prioritizing factors such as case complexity, severity, and costs across different levels.

As a result, our methodology identifies police units operating at full capacity, allowing the transfer of less complex, low-severity, and low-cost cases to neighboring units with spare production capacity. This surplus capacity enables fully operational units to concentrate on critical cases that otherwise might be overlooked.

Wednesday, 8:30-10:00 - Room: M1 (building: 101)

Stochastic inventory systems

Stream: Lot Sizing, Lot Scheduling and Production Planning

Invited session

Chair: Roberto Rossi

1 - On the Stochastic Inventory Problem Under Order Capacity Constraints

Roberto Rossi, Zhen Chen, Armagan Tarim

We consider the single-item single-stocking location stochastic inventory system under a fixed ordering cost component. A long-standing problem is that of determining the structure of the optimal control policy when this system is subject to order quantity capacity constraints; to date, only partial characterisations of the optimal policy have been discussed.

An open question is whether a policy with a single continuous interval over which ordering is prescribed is optimal for this problem. Under the so-called "continuous order property" conjecture, we show that the optimal policy takes the modified multi-(s, S) form. Moreover, we provide a numerical counterexample in which the continuous order property is violated, and hence show that a modified multi-(s, S) policy is not optimal in general.

However, in an extensive computational study, we show that instances violating the continuous order property do not surface, and that the plans generated by a modified multi-(s, S) policy can therefore be considered, from a practical standpoint, near-optimal. Finally, we show that a modified (s, S) policy also performs well in this empirical setting.

2 - Optimal Ordering Policies for Non-instantaneous Deterioration Items with Price and Stock Sensitive Demand under Inflation and Time Discounting

Kuo-Lung Hou, Li-Chiao Lin

In real life, such as fashionable commodities and high-tech products with short product life cycle, the length of the waiting time for the next replenishment is the main factor for deciding whether the backlogging will be accepted or not. On the other hand, such as seasonal items, first-hand vegetables, and fruits during the expiration period, there was no deterioration occurring immediately. In addition, several studies have shown that the impact of inflation on lot-sizing decision-making is often not negligible. We also noted that sales at the retail level tend to be proportional to the amount of inventory displayed. To reflect these phenomenon, this paper presents an inventory model for non-instantaneous deteriorating items with price- and stock-dependent demand under inflation and time value of money over a finite planning horizon. In the model, shortages are allowed and the unsatisfied demand is partially backlogged at the exponential rate with respect to the waiting time. We establish the theoretical results and provide an efficient solution procedure to find the optimal number of replenishment, the cycle time and selling price. Then the optimal order quantity and the total present value of profits are obtained. Finally, numerical examples are used to illustrate the proposed model. In addition, sensitivity analysis of the model parameters and some managerial insights are also discussed.

3 - A heuristic for an inventory control policy in a closed-loop distribution multi-echelon supply-chain with returns

Rodrigue Fokouop

This study tackles an inventory control challenge in a complex multi-echelon distribution system, drawing insights from Air Liquide's closed-loop supply chain with product returns. The inherent complexity arises from the distribution structure and the handling of returned cylinders. The goal is to frame this as a multi-echelon periodic review inventory control problem and identify the optimal control parameter.

Conventional stochastic programming approaches prove impractical due to the curse of dimensionality resulting from unmet customer demand and potential lost sales. In response, we introduce a heuristic approach, validated through simulation-optimization. This heuristic involves breaking down the multi-echelon distribution system into serial systems, optimizing target stock levels for each echelon, and aligning cumulative backorder quantities by aggregating shared echelon stock levels. The heuristic achieves a 0.74% average reduction in total inventory cost, demonstrating comparable results to simulation-optimization, with the notable advantage of rapid computation in seconds for practical real-world applications.

Applying the heuristic to real-world data enhances inventory control in the multi-echelon distribution system, leading to a 12.63% reduction in stock costs for regularly demanded products and a 21.89% reduction for sporadic demand. These findings highlight the benefits of a global inventory control approach in a multi-echelon distribution system.

4 - Dimensional Analysis and Solution Estimates of Economic Lot Sizing Problem

Joao Miranda, Mariana Nagy, Miguel Casquilho

The Economic Lot Size (ELS) problem allows a very efficient resolution, and it is often used as sub-problem of more complex Optimization problems. Namely, the ELS substructure can be found through suitable decomposition in diverse real world problems, such as batch scheduling, capacity expansion, facility location, production-distribution networks, or in the long range planning problem. An extensive study of single product uncapacitated ELS instances is carried out, and optimal estimates for the ELS problem are treated through dimensionless ratios and quotients: in one hand, by correlating the objective function's minimum value and the instance parameters; in the other hand, through a solution procedure that indicates the optimal binary solution and, in sequence, the production and stocking quantities. The related results are presented and analyzed, namely in what regards the application of dimensional analysis in the ELS instances at hand. Finally, future developments are outlined and discussed, including the potential extension to other Optimization problems of both dimensional analysis and associated approximation procedures.

Retail Distribution I

Stream: Retail Operations

Invited session

Chair: *Pedro Amorim*

1 - Order Allocation Optimization in a Fashion Marketplace

Sérgio Castro, Gonçalo Figueira, Bernardo Almada-Lobo

Order allocation is the dynamic problem of distributing incoming orders to fulfillment nodes. This problem appears in different sectors and contexts, where the nodes may belong to the same or independent vendors. We consider an Online Fashion Marketplace selling products owned by multiple vendors. In this setting, customers expect immediate feedback on their product fulfillment, such that order allocation decisions must be taken instantly. This particular Marketplace diverges significantly from prior studies in order allocation literature due to the consistent low sales volume per item across the majority of the product portfolio, and the daily fluctuations in inventory by vendors that introduce a notable level of uncertainty. Given the distinctive characteristics of this problem compared to existing literature, we propose an innovative methodology to generate heuristic fulfillment policies. Leveraging either Genetic Programming or Genetic Algorithms, we incorporate critical policy information, including shipping costs, basket coverage and stock depth into a machine learning pipeline to generate policies that are fast and effective. To assess the efficacy of the proposed policies, a comprehensive comparative analysis is conducted against the retailer's existing policy and a perfect hindsight policy, from which managerial insights are extracted.

2 - Designing Multi-Period Two-Echelon Last-Mile Delivery Networks with Multiple Capacity Levels under Uncertainty

Juan Carlos Pina Pardo, Pitehr Hurtado-Cayo, Matthias Winkenbach

We study the design of two-echelon distribution networks with facility sizing decisions over a multi-period planning horizon amidst demand uncertainty. This research is based on a real-world problem faced by a large consumer-packaged goods manufacturing and distribution company seeking to implement a multi-tiered distribution strategy via satellite facilities strategically located across the service area. The problem is formulated as a two-stage stochastic program with discrete recourse, where the first stage defines both the location and size of satellites, and the second stage defines which satellites to operate and how to serve customers. To solve the two-stage stochastic program, we develop an exact solution approach combining the integer L-shaped method and sample average approximation. Through extensive numerical experiments, we show the effectiveness of the proposed exact approach and present several managerial insights regarding facility location, the value of accounting for stochasticity, and the effects of explicitly incorporating facility sizing decisions when designing two-echelon distribution networks.

3 - Evolutionary Approaches to Solve the Dynamic and Stochastic Inventory-Routing Problem

Francisco Maia, Gonçalo Figueira, Fábio Moreira

Sequential-decision making is an active area of research in Operations Research (OR), where real-time decision-making, machine learning and data-driven approaches are stepping forward. The Dynamic and Stochastic Inventory-Routing Problem (DSIRP) is one of the most fundamental problems companies seek to optimize, given its meaningfulness at strategic and operational levels. The challenge at hand involves the integration of inventory management and vehicle routing problems while at the same time effectively handling the dynamic and stochastic nature of customer demands unveiled over time. A promising research path lies in combining Reinforcement Learning and OR to achieve novel inventory and routing policies with significant cost savings. Accordingly, Policy Function Approximation (PFA) emerges as an encouraging strategy. This research intends to give new insights into solving the single-item, single-vehicle DSIRP with a one-to-many endpoint structure, where decisions must be released periodically. Therefore, we propose novel delivery policies based on PFA, exploring two evolutionary algorithms, i.e. Genetic Programming and Genetic Algorithms. The proposed methodology enabled us to derive novel rules that present competitive results compared to several literature benchmarks, optimizing the balance between holding and stockout costs, reducing waste and decreasing travel distances.

4 - Logistical Support for the shipment of food products

Cecilia Montt, Astrid Oddershede, Luis Quezada

This paper explores the application of simulation in the redesign of dispatch processes to address delivery fulfillment and sustainable issues. The study focuses on a company that processes and supplies food to several employee cafeterias in a metropolitan city. The main objective of this company's logistics dispatch is the efficient delivery of final products using a fleet of refrigerated electric vans to ensure the sustainability. The challenge identified centers on intermittent delivery discrepancies, which lead to customer losses and product waste. By employing simulation and business process management (BPM), the administrative processing time has been reduced by 10 to 15 minutes. This time saving is crucial to food durability and to avoid delays associated with the unloading of incorrect or modified shipments. In addition, real-time fleet tracking has been established using specialized software. This tracking capability allows the company to analyze data continuously, with the goal of minimizing losses, reducing costs and promptly addressing delivery delays with up-to-date information.

■ WA-51

Wednesday, 8:30-10:00 - Room: M5 (building: 101)

Timetabling 2

Stream: Public Transport Optimization
Invited session

Chair: Pieter Vansteenwegen

1 - Analyzing Timetable Fragility

Marta Leonina Tessitore, Marcella Samà, Giorgio Sartor,
Carlo Mannino, Dario Pacciarelli

When looking at preventive approaches for disturbance management, the focus is on designing robust timetables that are able to absorb secondary delays. Following the recovery robustness approach, we use the concept of timetable fragility to analyze the resilience of a nominal timetable, i.e., its ability to recover from primary delays with optimal corrective actions. Given a timetable and suitable objective functions, the fragility defines a special class of scenarios associated with each pair train/section and use them to identify the pairs where a primary delay is more likely to generate large knock-on delays. In particular, the objective function should reflect real-time decision-making criteria adopted by dispatchers. Since no single, universally accepted measure exists, we explore some of the most common objective functions, e.g., the minimization of the max delay, or the minimization of the sum of consecutive train delays at the last station of their routes. Building on the concept of fragility maps, we propose additional analyses, including exploring the impact of precedence constraints in optimal dispatching and sensitivity analysis of the optimal solution. Considering real-life scenarios from a busy railway line in Norway, we discuss several potential uses of the fragility to improve decisions at different levels of the railway planning process, including dispatching, timetable design, and network design.

2 - Heuristics for recovery robust periodic timetabling

Vera Grafe, Anita Schöbel

An important aspect of optimising public transport is finding a good timetable. On the one hand, short travel times are important from the passengers' point of view. On the other hand, tight timetables without buffer times are prone to delays, which are inevitable in practice and highly dissatisfactory for the passengers. Hence, a good timetable should also have some degree of delay resistance. Often a periodic timetable is desirable, i.e. a timetable which repeats in a regular pattern (e.g. every hour). However, delays do in general not occur periodically, so many robust timetable models only consider aperiodic timetables. In our work we apply the concept of recoverable robustness to periodic timetabling with aperiodic delays, resulting in the integration of two well-known problems: the periodic event scheduling problem (PESP) and delay management (DM). We show how we can bridge the gap between the periodic PESP and the aperiodic DM, yielding MIP formulations. However, solving the problem to optimality is unrealistic for large instance due to its high complexity. Therefore, we pursue heuristic approaches. We present iterative heuristics computing periodic timetables with increased robustness at the cost of only a small increase in the nominal travel time.

3 - Integrated optimization of demand management and timetabling of an urban transit system: A Benders decomposition approach

Yahan Lu, Lixing Yang, Jiateng Yin, Shadi Sharif Azadeh

The intelligent upgrading of metropolitan rail transit systems has made it feasible to implement delicate demand management policies that synergize multiple strategies in practical operations. The interdependence of supply and demand motivates the following question: How to scientifically and rationally develop demand-side management policies and supply-side capacity allocations to enhance the whole urban rail transit ecosystem? To answer this question, we propose a mathematical and computational framework that optimizes train timetables, passenger flow control, and trip-shifting strategies, incorporating

emerging trip reservations and service fairness. The problem is formulated as a nonlinear programming model and solved using a Benders decomposition-based solution algorithm within the branch-and-cut method. To further improve the computational efficiency, a novel decomposition method, and valid inequalities are developed, which decomposes the model into a train timetabling problem combined with partial passenger assignment and a passenger flow control problem. The computational results of real-world case studies based on the Beijing metro show that our solution method outperforms commercial solvers in terms of computational efficiency. Our proposed integrated optimization method consistently leads to a reduction of 16.3% in the system-wide waiting time of passengers while simultaneously reducing the number of operated trains.

4 - A MILP model to improve the robustness of a railway timetable in a bottleneck area: a case study in Belgium

Inneke Van Hoeck, Pieter Vansteenwegen

Robustness is a crucial concept in the railway timetabling problem. It is often related to the ability of a timetable to absorb small delays and avoid the propagation of these delays. We propose a MILP model to improve the robustness of an existing microscopic timetable in a complex and heavily used part of the network. The objective is to maximize the buffer times between each pair of trains, leading to a good spreading in time of the trains. The timetable can be improved by adapting the timing and the routing of the trains. Since only a part of a larger network is considered, the allowed deviation from the initial timetable is limited such that the newly proposed timetable does not cause conflicts outside of the considered area. Depending on which properties the resulting timetable should have, certain constraints can easily be added by the user. Due to the flexibility of the proposed model, it can also be used to analyze and optimize alternative scenarios and provide more insight into the robustness of the timetable. The model is applied to a case study of a bottleneck area of the Belgian railway network, located just outside of Brussels. The traffic in this area is very heterogeneous, with InterCity, local, peak-hour and high-speed trains. The spreading objective is improved with 18% compared to the current situation, thus leading to a more robust timetable. Additionally, alternative scenarios, related to extending a line, adding trains and cancelling trains, are studied.

Wednesday, 8:30-10:00 - Room: 8003 (building: 202)

Models and algorithms for real-life combinatorial optimization problems

Stream: Combinatorial Optimization
Invited session

Chair: Maria Battarra

Chair: Anand Subramanian

1 - A mathematical formulation for a real-life single-track train timetabling problem

Renata Mendes, Teobaldo Bulhões, Bruno Bruck, Anand Subramanian

This study focuses on developing a mathematical model that addresses a train timetabling problem arising at Companhia Brasileira de Trens Urbanos (CBTU), a railway company in Brazil. The objective of the problem involves determining arrival and departure times at multiple stops along the network.

The operation of a railway system heavily depends on a well-organized timetable. Adherence to safety protocols regarding vehicle operations on tracks is also crucial. Therefore, the objective of this work is the allocation of routes and timetables for trains, while enhancing customer satisfaction and considering operational constraints.

The CBTU train line covers a 30-kilometer route from Santa Rita to Cabedelo, both cities located in the state of Paraíba, Brazil. Approximately 8 thousand passengers make use of the railway daily. Hence, determining a timetable impacts the lives of passengers needing safe, convenient travel in sync with their routines. Furthermore, trains must travel in opposite directions using a single track simultaneously, and collisions pose a significant risk if schedules are not carefully planned.

Preliminary results suggest that the developed formulation can handle small-scale instances. However, the current model could perform more effectively when dealing with real-life scenarios. The next phase of the research involves devising a stronger formulation and exploring (math)heuristic approaches capable of tackling larger instances.

2 - The Wildfire Suppression Problem: coordination of the fire fighting resources

Maria Battarra, Mualla Gonca Avci, Mustafa Avci, Gunes Erdogan

Wildfires are endangering forests, dwellings and the population. This study was motivated by informative discussions with members of the wildfire directorate in a province of Turkey, Natural Resources Wales, the UK Forestry Commission, and Forestry England. We introduce, model, and solve a wildfire suppression problem that involves the coordination of various types of fire-suppression resources, as we realised the literature models all types of fire fighting resources (i.e., fire engines, helicopters and razing teams) as generic resources, ignoring their different operational constraints and effects in extinguishing or controlling the spread of a wildfire. Two integer programming formulations for the problem are presented, the performances of which are evaluated on a set of randomly generated problem instances. Realistic operational constraints about the different firefighting resources are embedded, and the fire spread is simulated depending on the wind conditions. Dwellings, infrastructures and areas of naturalistic beauty are prioritised for protection. The results indicate that the proposed formulations are able to solve instances of realistic size. The importance of the right mix of resources employed in tackling a wildfire as well as their coordination are highlighted. A case study inspired by the Yatağan district of the Mugla province of Türkiye has been developed, and maps simulating the fire spread over time will be showcased.

3 - The maximum length car sequencing problem

Lara Pontes, Carlos Neves, Anand Subramanian, Maria Battarra

This study introduces a new variant of the car sequencing problem to support the operations of a Brazilian automotive assembly plant. We propose an integer linear programming (ILP) formulation to schedule the maximum number of cars without violating the spacing constraints associated with car options, such as air-conditioning or sunroof. In the studied plant, these violations lead to a complete stop of the assembly line, which is the least desirable outcome for the company. We also present valid combinatorial lower and upper bounds, as well as binary and iterative search algorithms to solve the problem when good primal bounds are not readily available. In addition, we develop an effective iterated local search algorithm to quickly obtain high-quality solutions, then used as a warm start to the exact methods. Computational results demonstrate that relatively low gaps are achieved for benchmark instances within a time limit of ten minutes, and we conduct an instance space analysis to identify the features that make the problem more difficult to solve. Moreover, the instances reflecting the company's needs are solved to optimality in less than a second. Finally, simulations with real-world demands, divided into shifts, are performed for a period of four months. In this case, we use the proposed ILP model in all shifts except the last one of each month, for which we employ an alternative model to sequence the unscheduled cars, adjusting the pace of the assembly line.

4 - Optimizing the usage of cut and fill materials in a large-scale railway construction project

Felipe Lemos, Bruno Bruck, Maria Battarra, Anand Subramanian

In this work, we investigate the problem of reusing dug materials in a large-scale railway building construction project. The project is inspired by a real-world scenario from HS2, the company responsible

for building a 225-kilometer fast train line in the UK. The company estimates that the dug material will amount to around 132 million tons, and material imported for construction will be around 20 million tons. The dug material can often be repurposed for fill operations to minimize environmental impact. In this research, we model the problem of allocating dug materials to fill operations, considering operational and financial constraints. We propose two approaches to solve the problem. The first one consists of an integrated MILP model, while the second one is a heuristic algorithm that initially solves a simplified version of the integrated model for each month of the time horizon, and then calls another MILP that tries to find a feasible solution. Both approaches were tested on instances generated based on real data provided by the company. Preliminary results show that the first approach is only capable of finding optimal solutions for small and medium sized instances. On the other hand, the second one is significantly more efficient in terms of runtime required to find feasible solutions, especially for larger instances, but it struggled to find the optimal solutions obtained by the first approach.

Pathways to Climate Resilience

Stream: Sustainable and Resilient Systems

Invited session

Chair: Francesco De Marco

Chair: Elise Miller-Hooks

1 - Computing transformation pathways towards a climate neutral European energy system with high spatial and temporal resolution

Manuel Wetzel, Karl-Kiên Cao, Shima Sasanpour

The transition of energy infrastructure towards climate neutrality poses significant challenges for infrastructure planners and policymakers. Large-scale energy system models play a fundamental role in evaluating alternative scenarios for future development and enabling informed decision making. However, modeling renewable energy sources and flexibility options requires high spatial and temporal resolution, resulting in some of the largest linear optimization problems tackled.

Various approaches have been developed to deal with this complexity, including heuristics, mathematical decomposition, and complexity reduction. This study combines the REMix framework with the parallel solver PIPS-IPM++ to compute transformation paths for the European energy system. This combination can provide insights into the ideal timing for converting natural gas infrastructure to hydrogen and explore the trade-off between investment rates and the remaining carbon budget.

First, this talk addresses the computational challenges of solving large linear optimization problems with parallel solvers and discusses the tuning of the decomposition approach to exploit the block structure. Second, it presents insights and key findings on the cost-optimal transformation path of the European energy infrastructure towards climate neutrality. These findings include spatial allocation of capacity and storage, as well as robust network topologies for both power grids and gas pipelines.

2 - Climate policy uncertainty, electricity production and credit risk: do banks enhance green investments?

Lorenzo Calò, Valeria Stefanelli, Pierluigi Toma

Credit risk in the banking sector is crucial in the current discussions on climate change and environmental sustainability. The transition from non-renewable to renewable energy sources, supported by the Paris Agreement, is the main strategy to mitigate the effects of climate change through the reduction of greenhouse gas emissions. Governments' tailored climate policies are key in this context to promote a greener economic pathway. Climate policy uncertainty places banks and their credit allocation decisions in a significant position, directly

influencing investment choices in the energy sector, including the development and adoption of renewable energy technologies. In this context, credit risk emerges as a crucial factor, as banks, the main lenders, guide the directions of energy investments by granting or withdrawing credit for various energy projects. This study aims to assess the impact of climate policy uncertainty on electricity generation in the U.S. from 1988 to 2015, focusing on non-renewable and renewable sources. The main goal is to investigate the effects that the CPU have on such energy sources. We employ the Fourier-ARDL model and Granger's causality test to explore the complex relationship between CPU and electricity production. The findings have significant implications for policymakers, managers, and banks, with regard to energy infrastructure investment decisions and lending decisions for the acquisition of such infrastructure.

3 - Identification of extreme weather events for the design of a climate resilient European energy system

Francesco De Marco, Giovanni Sansavini

Climate change impacts energy systems reliability. Extreme weather events, such as droughts and heat waves, can undermine the ability of technologies to convert energy and can exacerbate the demand for electricity, heating, and cooling. This causes unexpectedly high operative costs and, in the worst cases, inability to supply demand. Hence, it becomes crucial to consider the impact of more frequent and severe extreme weather events during the planning of a cost-optimal low-carbon energy system to ensure climate resilience. This work introduces a method to convert the output of the global climate model CESM2 into hourly-resolved energy-related metrics, e.g., capacity factor, by capturing the impact of weather on conventional, renewable technologies, and on energy demand. Such metrics are used to parametrize a multi-year transition pathway optimization problem of the European energy system until 2050. The resilience of the system with respect to extreme events is investigated through a scenario analysis. First, the system is optimized in a base climatic case; then, alternative extreme scenarios are generated via a boosting method that aggravates those short-term weather events that are most critical to the operation of the energy system. The new climatic time series are converted again as input of the optimization problem. The resulting climate-resilient systems trade-off investment and operative cost to guarantee reliable and clean energy in a climatically unstable future.

Network Design and Line Planning for Public Transportation 2

Stream: Public Transport Optimization

Invited session

Chair: Rowan Hoogervorst

1 - Integrated timetabling, vehicle scheduling, and dynamic capacity allocation under demand uncertainty

Dongyang Xia, Jihui Ma, Shadi Sharif Azadeh

The Integrated Timetabling and Vehicle Scheduling (TTVS) problem has extensive applications in all sorts of transit networks. Recently, the emerging modular autonomous vehicles composed of modular units have made it possible to dynamically adjust on board capacity to further match space-time imbalanced passenger flows. In this paper, we introduce an integrated framework for the TTVS problem for a fixed line dynamically capacitated modularized bus network, taking the time-varying and uncertain passenger demand patterns into account. The modularized bus network comprises units that can be (de)coupled and rerouted to other lines through the network at different times and locations to respond to time-varying demand. We formulate a stochastic programming model to jointly determine the optimal robust timetable, dynamic formations of vehicles, and cross-line

circulations of these units, aiming to minimize the weighted sum of operational and passengers' costs. To obtain high-quality solutions of realistic instances, we propose a tailored integer L-shaped method coupled with valid inequalities to solve the stochastic mixed-integer programming model dynamically through a rolling horizon approach. An extensive computational study based on the real-world operational data of the Beijing bus network shows the effectiveness of the proposed approaches.

2 - Designing public transport networks via symmetric generalized optimum requirement graphs

Piyalee Pattanaik, Irene Heinrich, Philine Schiewe

Network design is a fundamental problem in public transport planning, fostering sustainability and efficiency. Here, we model the problem of reducing a given street network to a public transport network as a Generalized Optimum Requirement Graph (GORG) Problem. Our aim is to uncover a sub-graph within a fixed edge budget that minimizes routing costs associated with demand, where routing costs encapsulate the summation of all shortest path costs weighted by demand. When considering orb-webs, as an abstraction of circular cities, we can exploit their symmetry and a reduced solution space. We show that finding optimal symmetric generalized optimum requirement graphs is nevertheless NP-hard in general and identify polynomially solvable cases. By comparing integer-programming based solution approaches for both the general and the symmetric GORG problem, we demonstrate the computational efficiencies of the reduced problem space. Allowing only symmetric solutions, however, also influences the solution quality and introduces the so-called "price of symmetry." We analyze the influence of the budget and the underlying cost structure on the price of symmetry and show that especially for a Euclidean cost structure, generic and symmetric solutions have almost identical routing costs. Moreover, beyond a global perspective on routing costs, our evaluation extends to assessing the fairness of solutions across passenger groups.

3 - Integrated Vehicle Circulation and Periodic Timetabling Optimization with SMT

Florian Fuchs, Thomas Spanniger, Francesco Corman

Our study presents a novel approach to optimizing the Periodic Timetabling Problem (PESP) and Vehicle Circulation in the Rhätische Bahn Network (RhB-Network) using Satisfiability Modulo Theories (SMT). Like traditional Mixed Integer Programming (MIP), our methodology utilizes the Event Activity Network (EAN) to model railway timetable events and activities. However, our approach encodes the PESP and vehicle circulation constraints within an SMT framework, extending SAT with difference logic. This extension allows for high-resolution time calculations, addressing the scalability limitations of existing SAT methods. Furthermore, we use selectable activities, enhancing the model's capability to incorporate vehicle circulation effectively during train scheduling and routing. Empirical analysis on a large scale, Swiss Railway Network reveals that although MIP and SMT solvers show comparable performance on smaller instances, the SMT solver significantly outperforms on larger scales, consistently finding optimal solutions. In particularly challenging instances, we achieve a reduction in computation time by a factor of 100 or more, illustrating the value of SMT-based methods in solving complex scheduling problems and advancing public transport optimization.

4 - Integrated route selection and redesign of the surrounding bus network for a new BRT line

Rowan Hoogervorst, Evelien van der Hurk

In this talk, we consider the development of a new BRT line and the redesign of the surrounding bus network to best match the new line. Here, we consider the integrated problem of selecting a route for the BRT line as well as line planning and frequency setting for the surrounding bus lines. The route for the BRT line can be chosen from a selected set of edges within a graph, while the surrounding bus lines are chosen based on a given line pool. Moreover, travel time and operational cost benefits can be obtained for surrounding bus lines due to the possibility of using BRT segments, which allow for increased speed and reliability. The objective of our problem is to minimize the passenger travel time and operational costs, where we integrate the routing of the passengers as well as line capacities into the model. We

propose a column-generation approach to solve this problem, where columns correspond to possible travel paths for passengers. Our approach is tested both for artificial instances as well as a case study for a new BRT line in Greater Copenhagen.

Wednesday, 8:30-10:00 - Room: S02 (building: 101)

MOST - MaaS & Innovative Services for Sustainable Mobility

Stream: Transportation

Invited session

Chair: Michele Ottomanelli

Chair: Aleksandra Colovic

1 - Planning and managing MaaS services

Marilisa Botte, Alessia De Falco, Ilaria Henke, Fiore Tinessa, Luigi Pariota

Mobility as a Service represents a topical theme in the current research and innovation ecosystem thanks to its potential disruptive impacts on transportation systems. The current literature shows a lack of tools and examples which could provide public authorities (or other relevant stakeholders) with useful decision-making support to quantitatively evaluate the expected effects of the introduction of MaaS packages on the transportation system, thus conceiving and planning them most properly. Many works in the literature evaluate MaaS effects by means of agent-based simulation tools which miss the systemic and strategic perspective typical of the planning stage. Other contributions fully neglect the planning task, by evaluating the effects of MaaS services as empirical evidence from pilot programs and field trials. Therefore, this contribution proposes a decision support system for estimating the effects of the introduction of MaaS services on different stakeholders (i.e., MaaS users, other transport systems customers, transport operators, etc.) based on the aggregated representation of demand (in a four-step approach) and supply systems in the presence of MaaS. As a first attempt, the proposed approach has been tested on a toy network to show an example of the quantitative evaluation of the adherence of different MaaS packages to the territorial contexts and governance goals pursued. The proposed contribution appears to be unique in the current research literature.

2 - Urban multi-vehicle safety-critical environment for Connected and Automated Vehicles: MASA living lab in the context of Spoke 6

Andrea Castellano, Luca Bedogni, Giulia Berardinelli, Marko Bertogna, Carlo Augusto Grazia, Martin Klapez, Elisa Landini, Marco Mamei, Alessio Masola, Marco Picone, Enrico Rossini

Nowadays, vehicles are able to drive autonomously in specific contexts. Spoke 6 project, part of the Italian National Centre for Sustainable Mobility (MOST), aims to contribute to developing an ecosystem of research and testing labs to promote the deployment of Connected and Autonomous Vehicles (CAV). This development will result in a network of permanent facilities for collaborative research, promoting technology transfer, increasing technology readiness in real-world contexts, and facilitating large-scale adoption of automated vehicles. In this context, Spoke 6 is extending the Modena Automotive Smart Area (MASA) to create an Urban Living Lab for CAV testing and data collection in a real urban multi-vehicle setting. The MASA facilities have been outfitted with traffic monitoring systems (based on smart cameras, RSUs, and OBUs) to enable the implementation of safety-critical scenarios. In this case, communication between infrastructure and road actors can broaden the electronic horizon and raise awareness of the traffic situation. In line with the project's pillars, this living lab is producing outcomes on: (i) Simulation, with the development of a Digital

Twin of the MASA to reconstruct the environment and visualize real traffic data; (ii) Vehicle Platforms, by equipping an automated vehicle with communication modules and an innovative HMI; (iii) Datasets, with the collection of environmental and driving data to design and test automated driving modules.

3 - Unleashing Mixed Integer Linear Programming: Optimal Shuttle Routing Solutions for Enhanced Urban Mobility

Marco Fabris

Efficient urban mobility is paramount in the evolving landscape of Mobility as a Service (MaaS). This study tackles a shuttle routing problem within this framework, akin to the orienteering problem, aimed at optimizing existing transportation networks. The problem involves optimizing shuttle routes through a directed graph representing an urban network, where nodes correspond to shuttle stops and edges depict road connections with associated travel times. Users at stops need to reach a common destination under specific time constraints, including arrival time and a tolerance window. The primary objective is to maximize passenger count while adhering to these constraints and operating within a predefined service time window. A mixed integer linear program (MILP) has been developed to obtain exact optimal solutions, so far demonstrating efficacy for networks of up to 15 nodes within reasonable computational time. The MILP discretizes shuttle time resources, thus ensuring solutions to be characterized by loop-free paths and optimal time schedules for the picked-up users. Further refinements to this result consider practical limitations, such as the shuttle capacity, and fairness-based incentives for people in order to strategically foster this kind of mobility (e.g., by favoring remote nodes). This approach lays the groundwork for scalable solutions in terms of both urban networks and number of deployed shuttles, as well as for real-time data integration for dynamic scheduling.

4 - Optimal placement of electric vehicle charging stations in urban areas

Aleksandra Colovic, Mario Marinelli, Michele Ottomanelli, Samira Stivan, Vitti Federico, Federico Devalle, Andrea Demartini

Sustainable travel modes are considered as one of the main directions for moving towards more sustainable living in urban areas. The technology advancements of electric vehicles (EVs) have been receiving growing attention on global market. Still, the support of public authorities in pushing towards sustainable mobility paradigms and designing solutions for the deployment of charging infrastructures is needed. There are several papers in the literature that have dealt with the estimation of EVs charging demand, both on macro and micro level, the placement of EVs charging facilities and management of real-time operations of EVs. In this context, we propose a novel optimization model for the efficient placement of EVs charging stations by considering the influence of existing points of interest (such as restaurants, supermarkets, touristic places, schools, hospitals, etc.) and service radius of potential EVs facilities. Generally, the coverage of a charging point, expressed in terms of average time or distance to reach a charging station, is correlated with the willingness-to-use of EVs drivers. Also, the presence of a particular category of points of interest, within the predefined service radius, shows the attractiveness of charging location. The proposed model has been applied to a real network of the Lombardy region. Preliminary results are encouraging and push towards further developments.

Advancing mobility towards sustainable solutions III

Stream: Transportation

Invited session

Chair: Atefeh Hemmati Golsefidi

1 - An AGV scheduling problem based on partial charging policy

Wei Wang, Hui Sun

This paper studies a scheduling problem for automated guided vehicles (AGVs), in which a fleet of homogeneous AGVs are used to deliver parts to workstations in a shop floor environment. During delivery the batteries of AGVs can be recharged, in order to ensure all parts are transferred from a central warehouse to their respective destinations without stops. A partial charging policy, which allows to flexibly manage the charging operations for AGVs, is employed. The transportation tasks undertaken by each AGV and the charging operations on each AGV need to be scheduled. The objective is to minimize the makespan to complete all transportation tasks. A mixed integer programming model is presented to describe the AGV scheduling problem. A two-stage heuristic approach is proposed for problem-solving. For stage one, two metaheuristics, i.e., a genetic algorithm (GA) and a hybrid GA and whale optimization algorithm (WOA), are developed to assign transportation tasks to each AGV. For stage two, a rule-based heuristic is proposed to schedule the assigned transportation tasks and charging operations for each AGV. Computation experiments show that the proposed solution procedures can solve the scheduling problem effectively and efficiently.

2 - Effects of time-of-use electricity prices on electric vehicle schedules

Fabian Brockmann

In recent years, the share of electric vehicles (EVs) for freight transport increased. Transportation companies must create daily routes for these vehicles by solving the electric vehicle routing problem (EVRP). This is mostly done in the same manner as for traditional internal combustion vehicles but aspects regarding range and recharging needs are added to the problem. However, dealing with EVs brings up a new problem: The Charging Scheduling Problem (CSP). EVs have not only to recharge along the route but also at their depot after operating hours. This can be done either by simple plug-and-charge, manual timing, or an optimized schedule. An important aspect of flexible recharging solutions is the connection time of the EV to the charging device. Therefore, the schedule of an EV over the day (timeline) is important for the CSP. However, most EVRP consider electricity prices as a constant fuel cost and do not consider the volatility of electricity prices. We address this problem and show how to combine the EVRP with the CSP.

3 - Dynamic and incremental expansion of large scale fixed and mobile charging infrastructure in stochastic environment: A Benders decomposition based approach

Atefeh Hemmati Golsefidi, Francisco Pereira, Samitha Samaranyake

As electric vehicle adoption increases worldwide, the growing charging demand necessitates a well-thought-out expansion of public charging infrastructure; insufficient or improperly deployed infrastructure poses the real risk of slowing down the adoption of electric vehicles. Public charging networks are likely to develop into very heterogeneous systems with, for example, fixed and mobile chargers. This paper proposes a multi-period mixed-integer programming formulation for optimally placing both fixed and mobile chargers in stochastic environments with the goal of meeting time-varying charging demands at a minimum cost. To discover EVs' uncertain spatial and temporal behavior, the energy demand scenarios are generated from an existing agent-based simulation of EVs in Frederiksberg and Copenhagen municipalities. Large-scale demand scenarios for Frederiksberg municipality are extracted from the simulation and then fed to a two-stage stochastic optimization to find the optimal expansion of fixed and mobile charging stations. As this formulation leads to an NP-hard problem, we develop a Benders decomposition for solving large-scale examples. In addition, a new algorithm is proposed to get exact sub-problem solutions and their corresponding dual variables without using linear programming solvers. Detailed experimental results confirm the effectiveness of the approach, which can provide exact integer solutions in a short computational time for even large problem instances.

Large-scale Speed-sensitive Network Optimization

Stream: Optimization at Amazon

Invited session

Chair: Daniel Guimaranas

Chair: George Iosifidis

1 - Stochastic Glance-View estimator

Jean-Charles Croix, Marc Bataillou Almagro, Augustin Lombard, Mehdi Bennaceur

The promised delivery speed enjoyed by Amazon's customers when glancing over the website's items (ASIN) is the result of a cascade of planning algorithms. At the core of this cascade is the modelling of the expected speed given a network design and inventory allocation. In this work, we present a scalable probabilistic approach to estimate the future glance-view speed, enabling us to query inventory aware speed variations in micro seconds. The close formulae derived in this work decouples inventory coverage from glance-view count forecasting, allowing us to answer valuable what-if scenarios regarding inventory placement, or new site launches. This in turn can guide Amazon's multi-million network design initiatives from short to long term horizons.

2 - Speed-aware network design: a parametric optimization approach

Ugo Rosolia, Marc Bataillou Almagro, George Iosifidis, Amit Kumar, Georgios Paschos

Network design problems have been studied from the 1950s, as they have a wide range of real-world applications. In classical network design problems the objective is to minimize the cost of routing goods through a graph. We introduce a generalised version of such a problem, where the objective is to trade-off the speed at which goods can be sent to their destination nodes and the cost of routing them. Compared to standard time-aware network design problems, where speed is taken into account by adding deadline constraints - i.e., goods have to reach destinations before a target date - we introduce a coverage function mapping the set of goods served by origin-destination pairs for which we offer expedite delivery to the number of unique items for which fast delivery services can be offered. This coverage function models that sets of goods for different origin-destination pairs may not be disjointed, and it allows us to compute the share of unique items for which we can offer expedite delivery services, which we refer to as speed-coverage. To minimize routing costs while jointly maximizing speed-coverage, we leverage parametric optimization to reformulate the coverage function as a convex program with an exponential number of constraints. Then, we propose a sampling strategy to reduce the dimensionality of such a reformulation. We show that when considering the overall costs given by routing costs minus speed revenues, our approach outperforms the baseline by 8.36% on average

3 - Local Solver for Joint Connectivity and Timing Optimization for Amazon's Outbound Network

Philipp Loick, Jian Shen, Jean-Charles Croix, Tiphaine Rougerie, Mattia Neroni, Amit Kumar, Georgios Paschos

The goal of Amazon's outbound network planning is to offer customers fast delivery at minimum costs. Key decisions are the legs and sorts to connect sites (connectivity) and Critical Pull Times (CPTs). This problem is computationally hard to solve and was in the past decomposed into the connectivity and timing subproblems that were solved separately. This paper presents a local-search engine to jointly optimize connectivity and timing for Amazon's outbound network. It bundles a variety of scientific and engineering ideas to build optimized solutions efficiently.

MILPs for Vehicle Routing 2

Stream: VeRoLog - Vehicle Routing and Logistics
Invited session

Chair: Teobaldo Bulhões

1 - Two-Commodity Opposite Direction Network Flows for Vehicle Routing Problems

Konstantin Pavlikov, Niels Christian Petersen

This paper revises the two-commodity network flow modelling approach for the Capacitated Vehicle Routing Problem (CVRP) with identical vehicles. The flows of equally sized two commodities considered in this paper are organized in the opposite directions along the collection of routes assigned to vehicles. The resulting mathematical programming formulations allow to formulate a general, asymmetric CVRP (even with presence of Time Windows constraints) using $n(n-1)/2$ binary variables, where n is the number of customers involved in the definition of CVRP, which is the number of binary variables typically required for the symmetric CVRP only. The commodity flow formulations of the problem is a very flexible tool for modeling the problem that allows for various enhancements. For example, the family of Generalized Large Multistar valid inequalities can be incorporated in a commodity flow-based formulation of the problem without using a single extra constraint. In addition, the compact mathematical formulations of the problem are further improved using Rounded Capacity Inequalities at the root node. The computational study demonstrates that a wide range of problem instances from the literature can be solved to optimality (or suboptimality with relatively small optimality gaps) using a simple solution methodology that solely employs a standard mixed integer linear programming solver.

2 - On a Generalization of the Information Collection Problem

Esther Jose, Nastaran Oladzad, John Becker, Rajan Batta

In today's data-driven world, efficient collection of information is crucial. We generalize this on a graph and propose a model that can be applied to a wide range of information collection problems. To solve an information collection problem on a graph where nodes contain retrievable information within a specific range, we introduce a two-phase approach. In the first phase, we pre-process the graph to determine the information that can be collected by moving through edges of the graph. In the second phase, we use a mixed-integer linear programming (MILP) model to maximize the amount of valuable information collected by traversing the edges of the graph within a given time limit. We provide extensions that can accommodate additional assumptions such as varying speed, information degradation, and threat or detection avoidance. Our model has practical applications for any problem where an agent, sensor, or decision maker is collecting information from a space.

3 - Comparison of Formulations for the Family Capacitated Vehicle Routing Problem

Raquel Bernardino, Ana Paías

The family capacitated vehicle routing problem (F-CVRP) is an NP-hard problem that generalizes both the FTSP and the capacitated vehicle routing problem. The F-CVRP has practical applications in warehouse management in warehouses with scattered storage. We propose several compact and non-compact formulations to address the problem. These formulations are compared both theoretically and computationally. Additionally, sets of valid inequalities are also derived and tested computationally. A branch-and-cut algorithm is used as a solution method for the non-compact formulations. Computational results show that both the developed branch-and-cut algorithm and the best-performing compact model are suited to address small to medium-sized instances of the F-CVRP.

4 - A Unified Exact Approach for a Broad Class of Vehicle Routing Problems With Simultaneous Pickup and Delivery

Teobaldo Bulhões, Rafael Praxedes, Anand Subramanian, Eduardo Uchoa

The vehicle routing problem with simultaneous pickup and delivery (VRPSPD) is a well-known combinatorial optimization problem. It involves finding the least-cost set of routes, starting and ending at the depot, while simultaneously satisfying pickup and delivery demands from multiple locations within a single trip without exceeding the capacity of the vehicle. There are many variants of this problem, each one incorporating additional attributes such as a heterogeneous fleet of vehicles, time constraints, route duration, multiple depots, and decisions regarding depot location. In this work, we propose a unified formulation for ten of these variants, which were considered special cases of a generic problem denoted as heterogeneous location routing problem with simultaneous pickup and delivery and time windows (HLRP-SPDTW). To solve it, we developed a branch-cut-and-price (BCP) algorithm and validated it through extensive computational experiments on more than 530 benchmark instances. The proposed BCP algorithm successfully found optimal solutions for 44.3% of unsolved problems, attained 92.6% of known optima, and improved lower bounds for 69.9% of the instances that remained unsolved.

Wednesday, 8:30-10:00 - Room: S08 (building: 101)

Pricing and applications 2

Stream: Pricing and Revenue Management
Invited session

Chair: Maher Agi

1 - Customized airline offer management: inductive research as proof-of-concept of high-dimensional segmentation

Daniel Schubert

Airlines serve different customers. Developing customized offer and pricing strategies have become a strategic priority to airlines and have attracted operations research accordingly. The present paper tests the fundamental hypothesis of the offer management system architecture of Schubert et al. (2021) that aims to combine the simplicity of branded fares with the flexibility of unbundled ancillaries. The hypothesis is that the wealth of data available to airlines enables highly granular and high-dimensional segmentation based on multiple features of a particular customer search.

The hypothesis is tested through inductive research based on 202 million flight coupons of a major network airline between 2018 and 2023. The research observes customer choice probabilities differ depending on weekday of the booking. Next, it identifies a pattern. Customer choice probabilities also differ based on sales channel, flight characteristics, and customer loyalty status. Generalizing these findings, this research concludes with a new hypothesis that airlines can improve prediction accuracy of customer choices and hence display more relevant offers when considering these search features. If true, it presents a low-cost process to increase prediction accuracy with data readily available to airlines. The research is relevant to both airline practitioners and researchers for follow-up studies alike.

2 - Customer-Centric Dynamic Pricing for Free-Floating Vehicle Sharing Systems

Matthias Soppert, Christian Müller, Jochen Gönsch, Claudius Steinhardt

Free-floating vehicle sharing systems such as car sharing systems offer customers the flexibility to pick up and drop off vehicles at any

location within the business area. However, this flexibility comes with the drawback that vehicles tend to accumulate at locations with low demand. To counter these imbalances, pricing has proven to be an effective and cost-efficient means. The fact that modern systems rely on mobile applications for their communication with customers, combined with the fact that providers know the exact location of each vehicle in real-time, offers new opportunities for pricing. We develop a profit-maximizing dynamic pricing approach which is customer-centric, meaning that, whenever a customer opens the mobile application, the price optimization incorporates the customer's location as well as the customer's choice behavior. In particular, it considers the effects of prices and walking distances to available vehicles on the customer's rental decision. Further, the approach anticipates future vehicle locations, rentals, and profits. More specifically, we propose an approximate dynamic programming-based solution approach with nonparametric value function approximation. It allows direct application in practice, because historical data can readily be used and key parameters can be precomputed such that the online pricing problem becomes tractable.

3 - Impact of blockchain on product pricing and vertical differentiation

Maher Agi, Erfan Asgari

We consider a manufacturer who sells two vertically differentiated products: a high-quality product and a low-quality product. Using blockchain is assumed to have a multiplicative increase of consumer perception of the product's quality and a loss of consumer utility due to privacy concerns. It is also associated with a fixed cost implementation and a per unit marginal cost. Given this, we build a stylized model based on customer utility and self-selection to study the impact of using blockchain on the conditions of co-existence of the two types of product on the market, the products' optimal prices, their respective market shares, the manufacturer's profit and his differentiation strategy.

Preliminary results show that the two products will continue to coexist while blockchain is being used only if the loss of consumer utility due to privacy concerns is contained within a certain interval (neither too high nor too low). The results also demonstrate a cannibalization effect of blockchain, while the manufacturer's overall market coverage remains the same. Moreover, the results establish the sensitivity of the benefit from using blockchain to the level of differentiation between the two products, and the impact of blockchain usage on the product differentiation level.

Manufacturing scheduling with sustainability considerations

Stream: Project Management and Scheduling
Invited session

Chair: *Federico Perea*

1 - Scheduling Automated Stacking Cranes in Container Terminals

Sameh Haneyah

Container terminals are crucial links in the global supply chain. These facilities operate in a highly dynamic environment. In this context, a main logistic challenge is scheduling the container handling equipment to execute the container transport and handling operations efficiently and effectively. We research the objectives and optimization strategies to deploy in scheduling and dispatching container handling equipment, in automated container terminals. In this effort, we review literature on scheduling and dispatching in container terminals, model the container terminal scheduling problem and address different solution methods. We decompose the problem and focus on the Automated Stacking Cranes (ASC) scheduling problem. This problem addresses

trade-offs such as delivering outbound containers to the transfer zones just-in-time versus delivering the containers early to avoid extra handling in the yard. The choices made on when to schedule container moves have a direct impact on the space utilization in transfer zones and on the minimization of unnecessary travel by the ASCs. In this study, we formulate the ASC Scheduling problem and discuss an on-line scheduling method.

2 - Scheduling manual operations on tire manufacturing machines

Mario Flores Gomez, Stéphane Dauzere-peres, Nabil Absi

Michelin, founded in 1889 in France, has evolved into one of the world's leading tire manufacturers. The company's commitment to research and development has propelled it to the forefront of tire technology, ensuring that its products meet the evolving needs of its various clients. This presentation is motivated by a real tire production line which, even though it is highly automated, still requires more than one operator to run. Operators play a crucial role in verification processes and are instrumental in resolving unforeseen issues. Our goal is to schedule the operations on the production line more efficiently, but also to guide the operators when random event occur. Actually, some of these random events should be considered when determining the schedules. The problem at hand can be defined as a flexible job-shop scheduling problem, where the routing of the operations of each job includes automated and manual operations. As all the automated operations are performed by the same machine, we are interested in scheduling the manual operations that should be assigned to and scheduled on one operator among the eligible operators. The objective to minimize is the flow time of the tires for a given team of operators. The presentation will detail how the problem is modeled and introduce the solution approaches for the deterministic case and for the stochastic case where random events are taken into account. Computational experiments on industrial data will be discussed.

3 - Scheduling on parallel metrology tools for risk minimization

Mathis Martin, Claude Yugma, Stéphane Dauzere-peres

In semiconductor manufacturing, product reliability and quality are crucial, especially for critical applications such as automotive or robotics. Hence, the outputs of production machines are measured through control operations performed by metrology (measurement) tools. As these tools become increasingly expensive, optimizing their use to minimize the risk is essential. Risk indicators can be used to prioritize lots in metrology. This work relies on the "Wafers at Risk" (W@R), which is the number of lots processed on a production machine between two lots that are measured. Each lot selected to be measured induces a gain (risk reduction) on the W@R of each of the production machines on which the lot was processed, and the earlier the lot is measured, the earlier the gains are obtained. In this presentation, we introduce a scheduling problem on parallel machines where the total risk reduction over time is maximized. Compared to classical parallel machine scheduling problems, computing the criterion requires to consider how the W@R of all production machines evolve when lots are measured on all metrology tools. To ensure the synchronization between metrology tools, time-indexed binary variables are required in the mathematical model of the problem. Various solution methods have been proposed, including a column generation approach, a greedy heuristic, and a Greedy Randomized Adaptive Search Procedure (GRASP). Numerical results will be presented in the conference.

4 - Acceptance Ordering Scheduling Problem: The impact of an order-portfolio on a make-to-order firm's profitability

Federico Perea, Juan Camilo Yepes Borrero, Mozart Menezes

Firms' growth, the darling measure of investors, comes from higher revenues. Thus, sales and marketing departments make extreme efforts to accept as many customer orders as possible. Unfortunately, not all orders contribute equally to profits, and some orders may even reduce net profits. Thus, saying no (i.e., not accepting an order) may be a necessary condition for net profits growth. For understanding the impact of rejecting orders on profitability, we propose an order acceptance and scheduling problem (OAS). Although the OAS has extensively been studied in the literature, there is still some gap between these papers and real-life problems in industry. In an attempt to close that gap, the

OAS we propose considers orders revenues, machines costs, holding costs and tardiness costs. We develop a mixed integer linear programming (MILP) model for solving this problem. Since the complexity of the problem makes it impossible for the MILP to solve large-scale instances, we also propose a metaheuristic algorithm. Numerical experiments show that the metaheuristic finds good quality solutions in short computational times. In the last part of the paper we confirm some managerial insights: higher holding and tardiness costs imply a lower acceptance of orders, forcing production has a concave negative impact on net profits, and accurately estimating costs is essential for good planning.

1 - Deterministic Model for Optimal Industrial Parks Location: The Case of Indonesia's Nickel Industry

Hasan Nur, Aadhaar Chaturvedi, Valery Pavlov

Industrial parks play a crucial role in facilitating the rapid industrialization of many emerging economies countries. However, planning these parks is complex, and their success hinges on strategic location decisions. This study proposes a mixed-integer linear programming formulation to determine the optimal locations of industrial parks to minimize total costs. It integrates large-scale actual distance measurements and multi-mode transportation considerations, capturing geographical nuances more realistically. Recognizing the energy-intensive nature of industries, the model incorporates transportation costs associated with energy sources. Real-world data sourced from the Indonesian nickel industry lends practical relevance to the proposed model within limited facility location studies with real-world applications. The case study examines 81 potential park locations, 139 nickel mining, and 20 coal mining sites, resulting in over 13,000 variables. Leveraging OpenSolver, optimal solutions are obtained within 15 seconds. The analysis unveils two optimal industrial park locations alongside capacity, raw materials, and energy supply allocation to selected industrial parks. Insights from sensitivity analysis include the pronounced influence of land acquisition, sea transport costs, and the elevated total costs associated with single-location industrial parks. Future research will explore uncertainty parameters relevant to the context of emerging economies.

2 - Combining MADM and MODM for allocating biomass conversion plants in Southwest Germany

Andreas Rudi, Frank Schultmann

Optimizing biomass supply chains necessitates the allocation of feedstock supply and biomass conversion facilities. This presentation introduces an innovative approach that combines Multi-Attribute Decision Making (MADM) with Multi-Objective Decision Making (MODM) to harmonize diseconomies of supply with technological economies of scale, thereby evaluating various biomass valorization pathways. Leveraging MADM and GIS-based location analysis, we establish a comprehensive location suitability criterion integrated into a two-fold linearized Mixed Integer Linear Programming (MILP) model, incorporating economic and ecological objectives. The multi-objective formulation is efficiently solved using the augmented epsilon constraint method. Finally, we employ the Technique for Order Preference by Similarity to an Ideal Solution (TOPSIS) method to assess the location decision of biomass conversion facilities and determine optimal designs for biomass supply chains. This approach not only estimates the potential for energetic or chemical biomass valorization in Southwest Germany but also facilitates strategic decision-making by integrating multi-criteria location analysis. By elucidating the specific methods

employed and outlining potential outcomes, this research contributes to the advancement of location analysis methodologies in the context of biomass supply chain optimization.

3 - Extending service locations optimally

Ashutosh Mahajan

We consider a firm that provides offline services through many branches to a population spread over a large geographic area. The firm is interested in opening additional satellite facilities in addition to its branches to improve its reach and attract new customers. Such facilities are also intended to relieve existing branches of low-value services so that they can focus on activities more valuable to the firm. Based on data available from a large bank in India, we create a model for deciding which locations are suitable for adding more satellite facilities. The model considers the footfall data of the existing branches, their geographical information and transactional data.

Machine Learning and Optimization in Ports

I

Stream: OR in Port Operations

Invited session

Chair: Frederik Schulte

1 - Container Terminal Energy Management and Operations Planning Under Uncertainty with Learning-based Onshore Power Scenarios

Xinyu Tang, Frederik Schulte

Container terminal operators reduce the energy costs in container terminals by implementing a demand response system, which can shift energy consumption typically through energy prices. We investigate operations planning and energy management through demand response to reduce energy-related costs. We propose a two-stage stochastic mixed integer programming model with energy-related costs as part of the objective function. The considered operations include vessel scheduling at berths, temperature control of refrigerated containers, and allocation of handling capacity of quay cranes, yard cranes, and automated guided vehicles to serve each vessel. Various scenarios for vessel arrival times and electricity prices are explored to represent the uncertainty of energy demand and supply, respectively. Moreover, onshore power supply (OPS) will become an increasingly important part of energy consumption in ports. We develop a machine-learning-based approach to determine realistic OPS demand scenarios in stochastic optimization. The suggested model is decomposed and solved using a progressive hedging algorithm. A case study of the Alterwerder container terminal in Hamburg is conducted to test the model. Results show a significant improvement when applying a varying real-time energy pricing scheme compared to a single energy pricing scheme.

2 - Pick-up and Drop-off Prediction for Tugboat Operations - An Inverse Optimization Approach

Frederik Schulte, Yuanfeng Xu, Mahnam Saeednia, Pedro Zatonni Scroccaro

Historical analysis of data related to the pick-up (i.e. the connection of the tugboat to the vessel) and drop-off (i.e. consequent disconnection) locations at ports such as the Port of Rotterdam shows a divergence from the scheduled plans, hypothetically related to factors such as weather, other scheduled activities for the tugboat, or other unknown factors. This poses challenges for the scheduling of tugboats and vessel-related activities, calling for an effective approach to predict the locations where vessels are picked up and dropped off. In this work, we propose an inverse optimization model to emulate the decisions of pilots in selecting the actual drop-off locations, aiming at learning the implicit decision models used by them. To this end, the proposed inverse optimization approach takes the actual decisions

as inputs and determines an objective and/or constraints that replicate these decisions. In the model, 'signals' are defined as the important factors that impact the decision of pilots such as vessel-, towage-, and weather-specific information. The model is constructed based on an orienteering problem, in which the objective function aims at maximizing the total score of a path calculated as the sum of the visited node scores. The output of the model minimizes a loss function defined as the difference between the predicted and actual locations. The results enable advanced anticipatory tugboat scheduling that outperforms conventional myopic approaches.

3 - RORO Stowage Planning with Reinforcement Learning *Alastair Main, Filipe Rodrigues, Dario Pacino*

Reduction of Greenhouse Gas (GHG) emissions in the shipping industry has been of great focus over the past years. Within Roll-on/Roll-off (RORO) shipping, GHG emissions can be reduced by decreasing the turnaround time at port calls. Decreasing the turnaround time for RORO vessels results in more time being available for sailing between port calls. As more time is allotted for sailing, the vessel can significantly reduce its speed and, thereby, fuel consumption. If RORO vessels have several port calls, the cargo is handled following an approximate First-in-last-out queue. Therefore, in some cases, cargo to be discharged at the port can become stuck behind cargo not to be unloaded. This results in a necessary re-handling of cargo, increasing time spent at the port. Optimizing the loading sequence, positioning of cargo, and cargo routing within the vessel reduces the number of cargo that needs to be re-handled. Prior research has utilized mathematical models and heuristics to solve similar problems. The authors present preliminary results for using a reinforcement learning framework to optimize the RORO stowage planning problem. Leveraging reinforcement learning allows for the development of an algorithm that can provide executable actions at the port based on current information in real time.

Novel Optimization Models in Finance

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management
Invited session

Chair: Stavros A. Zenios

1 - Tran2SP: Transformer-based Two-Stage Stochastic Programming

Woo Chang Kim

This talk introduces Tran2SP, a novel framework for solving two-stage stochastic programming (2SP) problems, which are characterized by making decisions under uncertainty. Traditional methods, while effective, often suffer from computational inefficiencies and the necessity to re-solve for new or altered instances. Tran2SP overcomes these challenges by employing the Transformer architecture to approximate the value function with piecewise linear functions, enhancing scalability and reducing computational demands. Unlike previous approaches that require extensive data or re-learning for modifications in the problem, Tran2SP adapts to changes efficiently, offering high-quality, robust solutions across various problem instances without the need to start from scratch. This advancement represents a significant improvement in solving 2SP problems, highlighting Tran2SP's potential to address the dynamic nature of uncertainties in optimization tasks. We further validate this approach through comprehensive experiments, confirming its effectiveness and robustness in practical applications.

2 - Reinforcement Learning for Portfolio Optimization in a Regime-Switching Model

David Saunders

We study a reinforcement learning approach to portfolio selection when the underlying asset price process follows a regime-switching diffusion model. An analytical solution to the HJB equation for the exploratory mean-variance model under regime switching is derived and implementation in practice employing a deep neural network will be discussed. Empirical results investigating robustness with respect to model mis-specification will also be presented.

3 - Sparse spanning portfolios and under-diversification with second-order stochastic dominance

Nikolas Topaloglou, Stelios Arvanitis, Olivier Scaillet

We develop and implement methods for determining whether relaxing sparsity constraints on portfolios improves the investment opportunity set for risk-averse investors. We formulate a new estimation procedure for sparse second-order stochastic spanning based on a greedy algorithm and Linear Programming. We show the optimal recovery of the sparse solution asymptotically whether spanning holds or not. From large equity datasets, we estimate the expected utility loss due to possible under-diversification, and find that there is no benefit from expanding a sparse opportunity set beyond 45 assets. The optimal sparse portfolio invests in 10 industry sectors and cuts tail risk when compared to a sparse mean-variance portfolio. On a rolling-window basis, the number of assets shrinks to 25 assets in crisis periods, while standard factor models cannot explain the performance of the sparse portfolios.

4 - Rational reaction to irrational behavior

Jorgen-Vitting Andersen

We study the problem where a population has to determine the truthfulness to certain commonly shared information. Problematics like this seems particular relevant in the current often tense political climate where spreading of false news repeatedly is at the center of accusation across the political aisle. To this aim we introduce a prototype model by considering "an index-of-truth" (IoT) and two types of agents: i) a percentage ρ of rational agents, and ii) $1-\rho$ of irrational agents. i) the rational agents use rational expectation in their decision making whether to believe in the given level of an IoT. By X we denote the uncertainty in the information used by the agents. If through rational expectations such an agent believe the IoT is right no action is taken. On the other hand, if the agent disagrees, a decision is taking to signal that the level of IoT is wrong influencing the value of the IoT index in proportion to the number of agents that reacts. ii) agents that are irrational on the other hand don't try to gauge the proper level of the IoT index, but rather try to position themselves in alignment of what they believe will be the future value of the IoT. The decision making of the irrational agents is also publically signaled and influence the IoT index in proportion to the number of agents that react We present an analytical expression showing how the range of the IoT index depends on ρ and X .

Last-Mile Delivery

Stream: VeRoLog - Vehicle Routing and Logistics
Invited session

Chair: Emanuele Manni

1 - Last-mile Delivery With Heterogeneous Crowdshipping and Service Levels

Tiago Monteiro, João Pedro Pedrosa, Ana Viana

Innovative strategies are emerging to handle the growing challenges of last-mile delivery, such as high operational costs and increasing customer expectations. Crowdshipping is a novel solution for last-mile delivery that offers a quick and cheaper way to provide same-day delivery and the flexibility to scale up or down the delivery capacity as needed: retailers, in addition to professionals, employ ordinary citizens (a.k.a. occasional couriers - OCs) to perform deliveries (this is the case of companies such as Amazon Flex and Roadie). The OCs

can be categorized into two classes depending on their commitment to the company: dedicated OCs, who actively register, provide a schedule with their availability, and can accept some proposed deliveries for compensation; and en-route OCs, who are in-store customers who make deliveries on their commute, also for a compensation. This work proposes a decision-support tool to empower decision-makers with insights into the trade-off between customer service levels and operational costs across different workforce compositions and compensation values. To achieve this, we conduct simulations where different compositions handle deliveries: exclusively the retailer's fleet, or the en-route OCs, or the dedicated OCs, or a hybrid combination of those workforces. As a collateral result, the traveled distance of different workforce compositions and compensation strategies is measured, offering insights into their environmental impact.

2 - Optimising Crowd-shipping With Parcel Lockers for Last-Mile Delivery

Mina Akbarpour, Stefan Ropke, Yu Jiang, Otto Anker Nielsen

The importance of increasing efficiency and capacity for last-mile delivery prompts e-commerce companies to explore alternative solutions, including the adoption of parcel lockers and leveraging crowd-shipping platforms. This study develops a holistic framework for optimising a parcel locker-based crowd-shipping system assisting the courier company's last-mile delivery. Our approach covers various aspects for operating such a system, including identifying the optimal locker locations, considering customers' stochastic choices in the delivery locations, and accounting for uncertainties in demand and crowd-shippers' availability. The proposed two-phase approach integrates generated locations improved by simulated annealing with a simulation-based mixed integer linear programming model for matching delivery tasks and optimizing vehicle routing. Specifically, once the locker locations are identified, a simulation-based approach is employed to determine the stochastic choices made by customers and their corresponding delivery tasks. The model then matches these tasks with either available crowd-shippers or the courier's own delivery vehicles, subsequently devising the most efficient routes for these delivery vehicles. Finally, the model is evaluated using last-mile delivery data from a region in Copenhagen. Our results highlight how the use of a parcel locker-based crowd-shipping system can enhance the efficiency of delivery operations for the courier company.

3 - Extending the Parcel Lockers' Solution to the Logistics Last Mile Problem

Boaz Golany, Yael Deutsch

We extend the model of designing a parcel lockers network as a solution to the logistics last mile problem, by choosing how many parcel lockers facilities to open, where to locate them, how many lockers to install in each facility, how to serve demand that exceeds the facilities' finite capacities, and what discounts to offer to customers to motivate them to prefer the lockers' option over the more convenient option of receiving the parcel at their doorstep. The objective is to maximize the total profit, consisting of the revenue from customers who use the parcel lockers solution, minus the facilities' fixed and operational setup costs and the different discounts offered to customers, depending on their travel distance and on their mode of pick-ups (on time, with minor or major delays, or by-passing the lockers and picking up directly at designated counters inside stores that were contracted for this task). The problem is expressed as a mixed integer linear program. We show that the model is tractable and can easily be solved by appropriate solvers available today. We present a few numerical examples to show how the model can be used in practice and demonstrate its sensitivity to additional constraints that might be imposed in certain circumstances.

4 - Park-and-Multi-Loop Routing for Last-Mile Delivery

Emanuele Manni, Tommaso Adamo, Gianpaolo Ghiani, Emanuela Guerriero, Gianluca Solazzo

This paper deals with the park-and-multi-loop routing problem, in the context of same-day delivery, in which a fleet of traditional vehicles equipped with several autonomous delivery robots (ADRs) leave from a depot to service a set of customer requests characterized by a delivery location and a time window. Each delivery route involves a main

tour of a traditional vehicle, which may stop at one or more parking slots, from which one or more subtours are carried out by the driver and the ADRs on the pedestrian network. The goal is to minimize the overall distance traveled by vehicles for traditional deliveries, as well as the walking distance covered by drivers and ADRs. For this problem, we propose an Adaptive Large Neighborhood Search (ALNS), in which the destroy and repair operators are parameterized, and the most appropriate parameter setting is constantly updated. The update phase is carried out by a reasoner, which analyzes the solutions and, according to some performance measures, identifies the most suitable routes to be destroyed and the parameterization of the repair operator. Computational results on a set of instances of varying size, derived from real data of several major cities, certify the quality of the approach, compared to an ALNS with classic destroy and repair operators.

1 - Dynamic vehicle routing and multi-objective task assignment for ride-pooling, last-mile logistics, and robotics

Javier Alonso-Mora

We move towards an era of smart cities and factories, where autonomous vehicles will provide on-demand transportation while making our streets safer, and mobile robots will automate processes in coexistence with humans. These applications require novel methods for real-time large-scale routing of thousands of vehicles and multi-objective task assignment. In this talk and building upon our seminal work on on-demand high-capacity ridesharing via dynamic trip-vehicle assignment, I will give an overview of our recent work in this field. I will first analyze some of the sources of uncertainty present in ride pooling systems, followed by a discussion of methods for predictive routing that utilize a model of future demand, how these systems could be combined with public transit, and how an equilibrium can be achieved. Secondly, I will discuss an extension of these methods for flash deliveries and a multi-objective optimization that enables us to design the required vehicle fleet accounting for the trade-off between quality of service and operation cost. Finally, and looking into a multi-robot task pickup and delivery problem, I will discuss how we can compute statistically distinct plans for multi-objective task assignment, which could later be employed by a user to select the desired operational point of the system.

1 - Risk-Sensitive Control in Portfolio Choice: Incorporating Ambiguity Aversion and Stochastic Factors

Chi Chung Siu, Guiyuan Ma, Dantong Chu, Wai Leong Ng

This paper explores risk-sensitive control in discrete-time portfolio choice. The investor considers stochastic factors and price impacts, including permanent and temporary effects. Ambiguity aversion towards model estimation errors of asset returns and stochastic factors is incorporated. The objective is to maximize the investor's preference for local mean-variance on investment returns, while accounting for mark-to-market profits and losses, execution costs, and penalties related to model estimation errors. Our study reveals that the investor's trading strategy may differ from the aim portfolio. Ambiguity-averse investors tend to trade more conservatively compared to non-robust cases. Trading decisions are influenced by factors like higher permanent price impacts and lower market resilience rates, with trading speed linked to ambiguity aversion. Simulation studies validate the effectiveness of the robust trading strategy, outperforming the non-robust approach. Mark-to-market profits and losses from permanent price impacts enhance the net Sharpe ratio. Incorporating risk-sensitive control

techniques in portfolio choice under uncertainty and ambiguity is crucial.

2 - A deep learning approach to forecasting commodity prices

Hayette Gatfaoui

Commodity prices are a strategic concern to countries and governments (e.g., energy or food security). Producers and end-users are sensitive to commodity price swings and volatility, which may imply lower profits and higher energy bills respectively. Commodity prices depend on supply and demand fundamentals but also specific drivers such as weather-linked seasonality and events, regional/country-specific infrastructures (e.g., bottlenecks) and regulatory/compliance constraints. Commodity price forecasting is important to allow market participants to hedge their risk exposures (i.e., losses due to large price swings). We apply a deep learning approach to few commodities for forecasting prospects. In the area of big data and artificial intelligence, deep learning allows for detecting key patterns in commodity prices and exploit them for forecasting purposes. Such an approach is data driven and relies on neural network analysis without requiring explicit fundamental factors. Moreover, the dynamic complex behavior of commodity prices is captured. A study of several forecasting windows is also performed. Besides, we also perform an improved deep learning approach by including very few key fundamental factors to check if these ones improve the forecasting degree of the method and/or increase the forecast horizon. Hence, we test for the usefulness of an augmented information space on the forecasting power and accuracy of deep learning in the context of few commodity markets.

3 - Venture Capital: Drivers of Growth

Mattia Margonari

The venture capital market, a private alternative investments form, has gained increasing attention and importance in recent years. Key industry metrics such as assets under management, average funding valuation, and the number of funds and startups have risen sharply, making 2021 a record year for the sector.

Several studies have shown that this industry contributes greatly to the development of countries' economies (LERNER; TÅG, 2013). The United States, a market where venture capital originated and which has been instrumental in its development, has long been able to benefit from the positive effects of a well-organized venture capital market: increased technological spillover effects, companies that are among the most highly capitalized on the stock market, and more employment (through VC backed companies) are just some of the benefits that the U.S. market has enjoyed (LERNER; NANDA, 2020; TOM, 2019). However, in the post COVID 19 era, capital raising and performance metrics are no longer in line with the industry's former standards and show a somewhat different landscape.

Against a backdrop of complex and difficult global context, this paper first examines what the growth drivers of VC are in relation to regional and national macroeconomic variables in Europe and what changes the venture capital market drivers have experienced from external shocks (e.g.: due to the COVID-19) (GOMPERS; GORNALL; KAPLAN; STREBULAEV, 2020).

Interpretable Optimization Methods and Applications

Stream: Data Science Meets Optimization

Invited session

Chair: Patrick De Causmaecker

1 - Feature-Based Interpretable Optimization

Sebastian Merten, Marc Goerigk, Michael Hartisch, Kartikey Sharma

For optimization models to be used in practice, it's crucial that users trust the results. This is influenced among other factors by the interpretability of the solution process. A previously introduced framework for inherently interpretable optimization models proposes to use decision trees to map instances to solutions of the underlying optimization model. Based on this work, we investigate how we can use more general decision rules to further increase interpretability and at the same time give more freedom to the decision maker. These decision rules do not map to a concrete solution, but to a solution set instead, which is characterized by certain features. A framework for MIP formulations as well as heuristics for generating such decision rules are presented. We outline the challenges and opportunities that these methods can present. In particular, we show the gain in solution quality that our approach can provide by using the conventional framework for interpretable optimization models as a benchmark and discuss the relationship between interpretability and performance. All methods are evaluated by using both artificial and real-world data.

2 - Explainability and Interpretability in Mathematical Optimization

Michael Hartisch

The evolution of mathematical programming has revolutionized our ability to address once-deemed intractable real-world problems on a large scale. Despite the efficiency of modern optimization techniques, the reluctance to accept provably optimal solutions persists, largely attributed to the perception of optimization software as a black box by many stakeholders. While well-understood by the scientific community, this lack of transparency poses a barrier to practitioners. We advocate for a paradigm shift by emphasizing the importance of incorporating aspects of interpretability and explainability in mathematical optimization. By clarifying the concepts of explainability and interpretability, we aim to bridge the gap between the advanced techniques understood by scientists and the accessibility required by practitioners. We will showcase initial steps taken in this direction and engage in a discussion on potential future directions.

3 - Leveraging Contextual Information for Robustness in Vehicle Routing Problems

Irfan Mahmutogullari, Tias Guns

We investigate the benefits of using contextual information in data-driven demand prediction to solve the robust capacitated vehicle routing problem with time windows. Instead of estimating the demand distribution or its mean, we introduce contextual machine learning models that predict demand quantiles even when the number of historical observations for some or all customers is limited. We investigate the use of such predicted quantiles to make routing decisions. We also evaluate the efficiency and robustness of the decisions obtained by both exact and heuristic methods. Our extensive computational experiments show that using a robust optimization model and predicting multiple quantiles is promising when extensive historical data is available. In scenarios with limited demand history, using a deterministic model with only a single quantile shows greater potential. Interestingly, our results also indicate that using appropriate quantile demand values within a deterministic model leads to solutions with robustness levels comparable to those of robust models. This is important because, in most applications, practitioners use deterministic models as the industry standard, even in an uncertain environment. In addition, because they are less computationally demanding and require only a single demand value prediction, deterministic models coupled with an appropriate machine learning model hold the potential for robust decision making.

1 - Convexification of optimization problems involving the Euclidean norm

Nikolaos Sahinidis, Anatoliy Kuznetsov

Several important open problems in chemical physics, mathematics, and operations research can be posed as nonconvex global optimization problems involving the Euclidean norm. For example, pairwise potential energy minimization, object packing and cutting, the kissing number problem, and planar facility location problems admit a representation of this form. We present new formulations and convexification strategies for problems involving the Euclidean norm and use them to solve several instances to global optimality for the first time.

2 - Random projections for quadratically constrained quadratic programming

Benedetto Manca, Leo Liberti, Pierre-Louis Poirion

We consider quadratically constrained quadratic programs (QCQP) in a general form with both linear and quadratic constraints. We will show that, if the number of quadratic constraints m and the number of decision variables n are large enough, there exist two random matrices T (with k rows and m columns) and R (with r rows and n columns) such that it is possible to apply them to the parameters of the original problem in order to obtain another QCQP with fewer decision variables and quadratic constraints which is easier and faster to solve. We will provide theoretical results showing that the projected program is related to the original one in terms of both feasibility and optimality and a procedure that exploits a solution of the projected program to obtain a solution of the original one. Numerical experiments on some different classes of QCQPs will be presented.

3 - Perspective Benders Cuts for Resource Allocation Problems with Separable Convex Costs

Kang Yang, Guopeng Song

We investigate two broad categories of resource allocation problems in which resources can be activated to fulfill the demand of one or multiple customers, respectively, with the objective of minimizing the total cost. Each resource incurs a fixed activation cost, and for each resource-customer pair, there is a variable allocation cost represented by separable convex functions. The traditional mixed-integer programming models for these problems are enhanced using the technique of perspective reformulation, which involves substituting each term in the separable objective function with its perspective term. In this work, we have developed a branch-and-Benders-cut algorithm to address the perspective reformulation models of these two general problem classes. Our approach incorporates two novel features. Firstly, a family of generalized Benders optimality cuts expressions suitable for perspective reformulation models, referred to as perspective Benders cuts, is derived, which are tighter than classic generalized Benders cuts. Secondly, we have developed a unified ad-hoc procedure, named reduce and recover, to efficiently separate perspective Benders cuts by solving the reduced quadratic subproblems. These features have led to a highly efficient solution method on these two general problem classes, which is verified through extensive computational experiments based on benchmark instances with four different classes of nonlinear allocation functions.

4 - A Safe Approximation of Distributionally Robust Problems Depending on Univariate Indicator Functions

Jan Rolfes, Jana Dienstbier, Frauke Liers

Driven by an application from chromatography, we model an optimization problem with linear objective subject to robust constraints that depend on uncertain particle size distributions (psd). The ambiguity set of our model can exploit information on moments as well as confidence sets. Moreover, we present a duality-based reformulation approach for distributionally robust problems, where the objective of the adversarial is allowed to depend on univariate indicator functions. This renders the problem nonlinear and nonconvex. In order to be able to reformulate the resulting semiinfinite constraints nevertheless, a safe approximation is presented that is realized by a discretized counterpart. Its reformulation leads to a mixed-integer linear problem that yields sufficient conditions for distributional robustness of the original problem. Furthermore, it is proven that with increasingly fine discretizations, the discretized reformulation converges to the original distributionally robust problem. Computational results for the chromatographic setting show that the safe approximation yields robust solutions of high-quality within short time.

1 - ESG factors driven asset management: a multi-layered approach for enhanced returns and risk mitigation

Salah Ayari, Hayette Gatfaoui

Using machine learning, we implement a novel investing strategy that integrates environmental, social, and governance (ESG) factors, coupled with economic and risk considerations to enhance portfolio performance. The strategy involves a monthly screening of the stocks within the Russell 3000 index based on three filters. The first filter considers the economic cycle and uses leading indicators to identify future outperforming sectors. Then, using a clustering algorithm, the second filter ranks the sector-winning stocks by their ESG scores and selects the top-rated stocks from each ESG group. Finally, the remaining stocks are grouped via a clustering algorithm that focuses on risk metrics. Within each cluster, we select the stocks which exhibit the lowest loss potential as measured by the conditional value at risk (CVaR).

The resulting stock portfolio is constructed with the selected stocks and related asset allocation is achieved by using a convenient optimization method. The proposed investing strategy demonstrates the potential for achieving a desirable balance between risk, return, and ESG considerations. It proposes an active portfolio management architecture based on three layers, the main drivers being the sector rotation and ESG-factor investing policy.

2 - Integrated optimization of operations and capacity strategy for drayage procurement in first-mile & LCL container logistics

George Vassos

Integrated container logistics rely on efficient management of first-mile and less-than-container-load (LCL) processes, particularly in drayage, which involves the short-distance movement of full container loads to consolidation centers or for modality changes. Given that shipping companies often engage external carriers for drayage operations, effective drayage procurement becomes crucial. This study introduces a dynamic programming approach to tackle the drayage procurement problem, integrating capacity planning optimization to devise a reservation plan that maximizes operational value. The scalability of the

proposed algorithm is assessed, with an extension to a model-free approach inspired by advancements in artificial intelligence aimed at mitigating computational burdens associated with executing the dynamic program for evaluating capacity plans. Execution times and optimality gaps between exhaustive and approximate dynamic programming methods are compared on small instances of the problem. Furthermore, the scalability of the approximate method to larger instances is demonstrated. Additionally, a parameterization of carrier capacities is proposed to further reduce the complexity of capacity optimization programming with minimal losses in optimality.

3 - Resource-constrained transmission maintenance scheduling problem

Amira Dems, Alain Côté, Mohamed Gaha, Quentin Cappart, Franklin Nguewou

The Transmission Maintenance Scheduling (TMS) is a strategic problem in asset management for electrical utilities around the world. It consists in generating an annual plan for the preventive maintenance of electric power transmission equipment. The resulting maintenance plan must ensure a continuous power flow during maintenance operations. It must also satisfy various constraints such as the stability of the network and the availability of skilled teams to fulfill the planned maintenance tasks. The proposed TMS problem is part of an important project for asset management at Hydro-Quebec (HQ). It is a variant addressing the human resource allocation constraints to ensure the feasibility of a maintenance plan (respecting the available number of technicians in each period). The problem is solved using a constraint-satisfaction approach and experiments are carried out on a HQ power subnetwork, with limits on the capacity of available electricians.

1 - Prosocial demand information sharing in a triadic supply chain with social preferences

Junlin Chen

We study a triadic supply chain with a retailer and two complementary suppliers. The retailer is close to the market and can privately acquire the market segmentation information, i.e., the proportion of prosocial consumers in the market, while the suppliers only know its distribution. The retailer reports the demand information of prosocial customers to the suppliers publicly, and the suppliers independently decide their own CSR investments to expand prosocial demand in the market under the positive externality of CSR investments. We consider supply chain members' social preferences, including the retailer's lying aversion behavior for the possible manipulation of information shared with suppliers, the suppliers' trust preferences towards the retailer's information sharing, as well as the suppliers' peer-induced fairness concerns caused by the possible free-riding given CSR investments' positive externality characteristics. The results show that: (1) Under full rationality, suppliers' CSR investments are independent of the retailer's report and the equilibrium is uninformative. (2) However, the existence of social preferences can facilitate the effective sharing of prosocial demand information in the supply chain, and enhance suppliers' CSR investments, leading to a win-win-win condition for supply chain members as well as prosocial customers. (3) The critical factors in achieving this condition are the matching between the retailer's lying aversion degree and the suppliers'

2 - Dynamics of equity and reciprocity in wholesale-retail price coordination equilibrium

Catarina Bessa, Tânia Pinto Varela, Ana Barbosa-Povoa, Cristóvão Silva, Samuel Moniz

Supply chains are portrayals of human behavior. Yet, traditional decision-support tools focus on economic goals, neglecting behavioral preferences such as fairness. Although fairness models are mainly grounded in equity or reciprocity concerns, recent efforts to model stakeholders' preferences within supply chains only consider the former. Given the inherent unfairness in supply chain systems, a move towards the accuracy of decision-support tools would be the modeling of reciprocity. However, based on two renowned models, a steppingstone was made by finding a coordination mechanism between a supplier and a retailer for a wholesale-retail price contract, in which two main concerns are raised: (1) the equity-based model tends to invariably set the disadvantage unto the supplier; (2) the reciprocity-based model fails to provide fully reciprocal outcomes. While these insights remain valid when profit requirements are jointly unattainable, we argue that these dynamics must be explored across a wider spectrum of parameters. To bridge this gap, a numerical analysis of these models is conducted and its implications for supply chains and its members are discussed. It is crucial to highlight that (1) the equity-based coordination ensures stability in the channel's profit when the retailer increases his demand for profit while; (2) the reciprocity-based model assures equal profits for both members; and (3) the behavior of both models moves closer as the production costs increase.

3 - Holding diverse market beliefs by firms: Information flow, profit performances, and channel structure

Zhongyuan Hao, Li Jiang

In representative settings, suppliers sell substitutable products through retailers to the market with uncertain demand and market competition is in quantity. Structure B comprises a monopolistic supplier and a monopolistic retailer. With respect to structure B, structure U includes competition between suppliers, structure D includes competition between retailers, while structure SC includes competition between two supply chains. A retailer has access to a demand signal useful for updating the forecast of market uncertainty. A supplier has no signal access but can offer a payment to a retailer, who decides whether to accept the payment and disclose signal to the supplier, termed information sharing. Suppliers and retailers hold diverse beliefs about market conditions. Knowing each other's market beliefs influences firms' ex-post operations policies and ex-ante profit perception. We demonstrate that holding diverse beliefs about market uncertainty by firms facilitates information sharing except in the presence of only retailer competition, in which case it deters information sharing. Exchanging market beliefs about market uncertainty among firms strengthens their incentive to engage in information sharing, which exerts mixed effects on their actual profits. By comparison, suppliers and retailers are more likely to benefit from exchanging market beliefs about market size, though it is inconsequential to information sharing.

4 - Newsvendor Overconfidence and Advertising

Meng Wu

Overconfidence, as the most robust behavioral bias, has been confirmed to be a leading cause of human newsvendors' pull-to-center (PTC) ordering bias. Most existing studies have focused solely on inventory decisions, overlooking the complexities that arise from the interface between operations management (OM) and marketing. As marketing and OM become increasingly intertwined and make decision-making more challenging, this paper examines the impacts of overconfidence on newsvendor's joint ordering and advertising decisions. Our study uncovered new decision biases that arise from overconfidence and have not been previously identified. Specifically, we found that overconfidence leads to over-advertising and a novel ordering behavior called the leapfrogging effect, where inventory can jump from underordering to overordering for medium-high margin products. Furthermore, our study shows that overconfidence can still result in a PTC-like effect for newsvendors who advertise. We also found that overconfidence has a more detrimental effect on profits for newsvendors with advertising. These findings highlight the need for overconfident newsvendors to be aware of choosing advertising because advertising can harm profits for overconfident newsvendors, while consistently improving profits for well-calibrated newsvendors. Overall,

our study emphasizes the need to consider the effects of behavioral biases on decision-making in more complex contexts, particularly in the operations-marketing

Applications of Knowledge and Technology

Stream: Knowledge, Technology, and Innovation

Invited session

Chair: A. D. Amar

1 - Transformation in the Maritime Sector via Autonomous Vessels and Eco-Friendly Fuels

Seyed Parsa Parvasi, Harilaos Psaraftis, Jasmine Siu Lee Lam

Mitigating climate impacts from greenhouse gases (GHG) is a complicated issue given the increasing energy demand. Utilizing environmentally sustainable vehicles and eco-friendly transport modes appears to be a highly effective strategy to tackle this problem. The European Union recognizes the crucial role of short-sea shipping (SSS) in the decarbonization efforts across the transport sector. The policy strategically aims to improve the share of SSS by encouraging a transition from road transportation to maritime alternatives. As part of a European project named AEGIS, this study seeks to use greener fuels in vessels by implementing a hybrid propulsion system that integrates methanol and batteries. The study explores the synergy of this propulsion system with autonomous vessels, intending to improve the competitive standing of SSS. The research undertakes a comprehensive examination of this innovative transportation on sustainability, implementing a cost-benefit analysis (CBA) that includes economic and environmental. In this research, a case study focused on the transportation route between the port of Hitra in Norway and the port of Rotterdam in the Netherlands, utilizing the concept of mother and daughter vessels. The results suggest that autonomous ships could potentially enhance the maritime sector's competitive edge. This could result in an increase in cargo transportation via this mode, thereby improving environmental sustainability.

2 - Selecting and Switching Knowledge Assets for the Firm Growth and Performance

A. D. Amar

Due to the emergence of robotics and autonomies, there has been a burst of interest in understanding the relationship between knowledge assets and firm performance. It is also observed that firms are keen to enhance performance by managing knowledge assets. On the research side, while much effort is going into this problem, clearcut answers have yet not come out. This research works on optimal answer to this problem by manipulating knowledge assets in their four prevalent forms, i.e., research and development, capital expenditure, selling, general, and administrative expenses, and property, plant, and equipment. We take performance as given by the rates of growth in seven most common metrics, i.e., revenue growth, cost of revenue, earnings from interest and taxes, profit, gross profit margin, cash flow, and times interest earned ratio. We formulate four hypotheses and conduct twenty-eight tests linking four knowledge assets to seven performance metrics. Using data from IT industries belonging to the SIC Code 737, we study the relationships and find that for different metrics, there are different knowledge assets. There is no one knowledge asset that will work for all performance metrics. It is true even for R&D. Therefore, to find the right knowledge asset for the desired performance metric, we design search methods employing selection maps to apply our findings to show how to strategically assign resources to the four knowledge assets for getting any targeted performance.

3 - Unravelling the Role of Perceived Value Dimensions in Shaping Millennials' Revisit Intentions: An Empirical Analysis of Homestays in the State of Uttarakhand, India

Santanu Roy, Amit Tariyal, Abhay Chamoli

A multitude of studies within the domain of tourism and hospitality sector have delved into the influence of perceived value on diverse aspects of consumer behaviour. Perceived value is regarded as a crucial element in comprehending a customers' tangible actions. The present study encompasses functional value, FV, social value, SV, and emotional value, EV, as the three distinct dimensions contributing to perceived value and explores their impact on millennial tourist satisfaction, MTS, and their revisit intention, MTRI, in the context of homestay experience in the Indian Hill State of Uttarakhand. Responses from 329 millennial tourist respondents were analysed. The results of multiple regression analysis reveal that an amalgamation of FV, SV and EV effectively explains 71.2% of the observed variability in MTS. Additionally, the calculated Durbin-Watson statistic is 1.913 indicating the absence of autocorrelation within the residuals, reinforcing the model's reliability. Digressing further, it is observed that FV and EV significantly impact MTS ($p < 0.001$; $\beta = 0.451$ $p = 0.002$; $\beta = 0.157$, respectively), but the same effect is not observed in the case of SV ($p = 0.347$; $\beta = 0.057$). Further, MTS is found to significantly impact MTRI ($p < 0.001$; $\beta = 0.868$). Homestays occupy a substantial section of the hospitality industry in this hill state. The findings have important implications for designing a strategy for augmenting millennial tourist revisit in the present context.

Production Optimization and Supply Chain Management of Green Hydrogen under Uncertainties

Stream: Energy Markets
Invited session

Chair: Evgeny Gurevsky

Chair: Victor Spitzer

Chair: Céline Gicquel

Chair: François Sanson

1 - Multistage stochastic optimization of an elementary hydrogen infrastructure

Raian Noufel Lefgoum, Jean-Philippe Chancelier, Michel De Lara, Pierre Carpentier, Sezin Afsar

The desired transition towards a hydrogen economy requires hydrogen costs to come down, through optimal choices of infrastructure design and operation. In this talk, we present an approach based on multistage stochastic optimization mixing design choices with operational decisions taken on an hourly basis. We consider an elementary hydrogen infrastructure which consists of an electrolyzer, a compressor and a storage to serve a transportation demand. This infrastructure is powered by three sources of energy (on site photovoltaics, renewable electricity through power purchase agreement, power grid). The modelling of the electrolyser covers its different functioning modes and the nonlinear relation between the production of hydrogen and the electricity consumption. The optimization problem is to minimize the operational costs over a week (while emphasizing the use of renewable sources), by making hourly decisions in an uncertain context. We consider uncertainties affecting on site photovoltaics production and hydrogen demand. We formulate a multistage stochastic optimization problem, and we develop suitable algorithms based on dynamic programming. We present numerical results for a given infrastructure design. Then, we consider various combinations of infrastructure design

and their subsequent optimal operation. With this, we discuss the optimal sizing of equipment, especially the sensitivity of electrolyzer and storage designs to the uncertainties.

2 - Feature-driven strategies for trading wind power and hydrogen

Lesia Mitridati

This talk presents a feature-driven model for hybrid power plants, enabling them to exploit available contextual information such as historical forecasts of day-ahead prices and wind power, and make optimal wind power and hydrogen trading decisions in the day-ahead stage. For that, we define and compare different linear and piece-wise linear decision rules. In addition, we propose a real-time adjustment strategy for hydrogen production. Our numerical results show that the final profit obtained from our proposed feature-driven trading mechanism in the day-ahead stage together with the real-time adjustment strategy is very close to that in an ideal benchmark with perfect information.

3 - Day-ahead lot-sizing under uncertainty: An application to green hydrogen production

Victor Spitzer, Céline Gicquel, Evgeny Gurevsky, François Sanson

Green hydrogen production via water electrolysis powered by renewable energy is essential to decarbonize key industries. However, it poses challenges such as ensuring hydrogen demand despite the uncertain availability of renewable energy sources. This work focuses on short-term electrolytic hydrogen production planning, considering a real case with a production site linked to a wind farm and the electricity grid. The wind farm provides fluctuating renewable electricity at negligible cost, while grid electricity incurs higher cost. The purchase of electricity from the grid has to be planned and declared a day ahead of production, i.e. before the exact availability of wind power is known. On-site hydrogen storage offers some flexibility for production planning, as it allows to produce hydrogen in advance.

The future availability of the wind power source is informed by forecasts subject to error, leading to a production overcost. A cohesive framework is introduced to handle this case study. First, a two-stage stochastic programming approach is presented to model this problem. Then, a probabilistic neural network is used to estimate the conditional wind power uncertainty and generate scenarios from the knowledge of past forecast errors. Finally, a time-efficient Benders decomposition approach is proposed, in which special features of our problem are exploited to speed up the resolution. A realistic simulation demonstrates the benefits of the presented approach.

4 - Dealing with stochasticity in the renewable hydrogen production

Patricio Reyes, Kelly Wagemann, Javier Hernanz Zajara, Santiago Fernández, Artur Garcia-Saez, Ricardo Enríquez

Energy arbitrage is a common practice in the European energy sector, which consists of taking advantage of differences in energy prices in the market. Companies use arbitrage to buy energy at a certain price, store it in batteries and later sell it at a higher price. Based on the same idea, hydrogen production can be considered renewable if the electricity supply mix contains a minimum amount of renewables. This work models the costs of an energy supply chain, identifying the best moments of energy purchase and sale over a time period, to control an industrial plan producing green hydrogen, taking into account a renewable share. Optimal conditions to operate the plant are unknown, as demand and production are uncertain variables at the moment to participate in the market. Our developed solution evolves from a deterministic model to an improvement with the introduction of stochasticity. The model is tested in realistic conditions with a custom package capable of solving the optimization problem for all the study cases. For a time horizon of 24 hours, the model is solved in less than half a second using state of the art solvers in an HPC cluster. To incorporate uncertainty, the variability of the energy price of the electrical grid is modeled by generating random scenarios. This is achieved by predicting time series using both traditional statistical methods and neural networks. It allows to reliably represent the variability of the operation over the energy market.

Wednesday, 10:30-12:00 - Room: 11 (building: 116)

Integrated planning in healthcare

Stream: OR in Health Services (ORAHS)

Invited session

Chair: *Sean Manzi*

Chair: *Melanie Reuter-Oppermann*

1 - An Integrative Approach to Scheduling the Pre-Treatment and Treatment Radiotherapy

Maxim Frankish, Broos Maenhout

Scheduling patients for radiotherapy within the oncology department is vital for ensuring timely and effective treatment. The patient's therapy consists of a sequence of pre-treatment consultations, i.e., preliminary investigations to define the required treatment, followed by the radiotherapy treatment sessions on linear accelerators. Timely scheduling of pre-treatment consultations is crucial to prevent unnecessary delays in radiotherapy treatment, thereby impacting patient health. Therefore, we suggest integrating both scheduling problems into one mathematical model formulation. We employ an online stochastic scheduling technique relying on simulation-based optimisation to solve the model. Additionally, we compare our proposed model with benchmark models utilizing a batch scheduling algorithm and ASAP heuristic. A comparison is made between our model and a sequential optimisation approach that subsequently solved the pre-treatment and treatment phase. We use information on the future arrivals of patients to provide a precise overview of anticipated patient flow. The input data was collected from a real-life case study. Our findings highlight the importance of integrating both phases in the scheduling process.

2 - Integrating case-mix planning and master surgery scheduling using branch-and-price

Sam Bakker, Broos Maenhout

In this research, we study the case mix planning problem (CMPP) accounting not only for the resources in the operating room department but also the most important resources in other departments such as for example, ward beds, ICU beds, and medical staff by considering the master surgery schedule (MSS) and its implications towards the demand for care in downstream ward units. The MSS allocates operating room time (OR time) among different departments, whereas the CMPP searches for the most profitable mix of patient types. Integrating the strategic and tactical patient planning decisions will reveal the impact of capacity decisions on bed utilization on the operational level and improves decision-making. Current literature treats these two as different, yet related problems, that are solved in a sequential manner. Most works on this topic first identify the optimal mix of patient types (case mix), and then construct an MSS based on this case mix. In this study, however, we try to solve the CMPP and the MSS in an integrated manner. The integrated problem is solved using branch-and-price and is applied to a real case study in a large Belgian hospital. Computational experiments show the effectivity of the presented approach.

3 - Examining inter-organisational care provision for people with disordered eating

Sean Manzi

Providing care and treatment for people with disordered eating is a complex undertaking requiring clinical input from multiple disciplines. The psychological underpinning of the disorder involves mental health services, the physiological impact brings in multiple inpatient and outpatient care services and support is required from General Practitioners in the community. The Integrated Care Board in Devon, UK have initiated an integrated care pathway for people with Anorexia Nervosa. However, diagnoses of Anorexia Nervosa account for only 14% of disordered eating cases. This study sought to understand the current care provision for people with other eating disorders to inform the development of defined care pathways for people with eating disorders other than Anorexia Nervosa. A network-based operational modelling approach was employed to analyse, the care provision for people with

disordered eating across Devon. This analysis was based on an integrated dataset containing data from the majority of NHS care providers in the geography. The most likely treatment pathways were simulated from the model to determine what the current provision of care looks like. We saw a high reliance on primary care services, community mental health teams and general internal medicine. The models and findings from this study are being further interrogated to inform the development of new care pathways to improve integrated care provision for this patient group.

4 - A metaheuristic approach for an integrated nurse routing and re-rostering problem

Anisha Maharani, Yasemin Arda, Véronique François

Hospital-at-home (HaH) provides short-term acute care to patients at home for a condition that otherwise would require inpatient admission. Having acute illnesses, the patient mix fluctuates. Furthermore, more accurate information about resource availability becomes known with time. Thus, operational plans have to be established taking into account this updated information. Given a baseline roster and patient requirements, simultaneous operational decisions on patient admission, nurse assignment, visit scheduling, and potential roster updates are taken for a weekly horizon, yielding a combined nurse routing and re-rostering problem. The integrated problem incorporates complex real-world characteristics related to patient admission, routing, rostering, and re-rostering constraints while ensuring continuity across consecutive planning horizons. A lexicographic objective function first maximizes the number of patients admitted to HaH and second minimizes the total working duration of the nurses. This is achieved by employing destroy and repair strategies based on a large neighborhood search. A guided local search is embedded to modify nurse rosters to further improve the solution. Infeasible solutions are allowed to be explored by relaxing time windows, rostering, and re-rostering constraints. The first results obtained by this algorithm will be presented, followed by a discussion about several challenges in balancing the different objectives of the studied problem.

Scenarios and foresight practices: Behavioural issues II

Stream: Behavioural OR

Invited session

Chair: *Martin Kunc*

1 - Using judgmental forecasting and scenario thinking for anticipating the future: what are the differences, the similarities, and the advantages of each?

George Wright

Judgmental forecasting is the domain of psychologists interested in forecasting and covers the areas of judgmental probability forecasting and the judgmental adjustment of time-series models, mostly at an individual-participant level. Closely linked is the Delphi method which is a group-based method. By contrast, scenario thinking was, until recently, the domain of practitioners interested in helping organisations make better decisions in the face of uncertainty. My paper discusses the role of subjective probability and outcome verification, and the focus on single point estimates as opposed to creating multiple, broad-brush anticipations of the future. Until recently, very little academic research has used experimental techniques to evaluate the quality of developed scenarios, but this position is changing. Additionally, recent work within the judgmental forecasting tradition has combined judgmental prediction with scenario storylines, a focus that has also become part of practice - for example, within the UK National Grid energy scenarios that are used for national policymaking. Clearly, scenario thinking is now becoming strongly established in practice -

perhaps as a response to the World's lack of preparedness for Covid-19 pandemic. I discuss the emerging need to develop and apply yardsticks of the quality of both the scenario development process and of the resultant scenario content. I outline my thoughts on guidelines for such standard setting.

2 - Navigating the path to future: Insights in fostering exploration in critical infrastructure systems

Simone Lombard, Heiko von der Gracht

Scenario and foresight practices enable organisations to explore new opportunities and innovate. However, the value contribution of these methods depends on whether managers are able to implement the findings. Behavioural issues such as risk avoidance, conflicting organisational demands, and inappropriate decision-making logics hinder this transfer. Organisations often tend to prioritise protecting their dominant value creation over exploring new opportunities. The research aims to understand how behavioral issues and subtle factors influence the initiation of exploration. The ongoing research examines exploratory foresight methods from an ambidexterity perspective. A bibliometric analysis was conducted to understand the variety of concepts and current discussion on ambidexterity. Our findings show that antecedents and capabilities, as well as the outcomes of ambidexterity are considered, while the actual management practices remain largely unexplored. Due to the complexity and idiosyncratic management approaches in companies, causality and management mechanism are difficult to research. For companies that provide critical infrastructure, innovation management must explicitly consider the impact on existing value creation, making it possible to explore factors and causal relationships. Further, we aim to understand multiple case studies in critical infrastructure systems and how management practices are re-configuring structures and resources to seize future opportunities.

3 - Incorporating stakeholders' behaviours in foresight practices. Insights from corporate engagement in climate change adaptation action-based scenarios

Fabrice Roubelat, Anne Marchais-Roubelat

Exploring scenario design as an anticipation of future actions, the purpose of this research is to examine the issues raised by the incorporation of stakeholders' behaviours in the process as well as in the content of scenario and foresight practices. Scenario literature may either refer to the engagement of multiple stakeholders in the scenario process (Bryson et al., 2016, Crawford, 2019, Mukherjee et al., 2020) or to the incorporation of stakeholder analysis in scenario design (Bradfield et al., 2015, Marchais-Roubelat and Roubelat, 2016). We discuss the lessons from an action-research on the engagement of industries in climate change adaptation (Roubelat and Marchais-Roubelat, 2022). The scenario design process implied the making of groups of stakeholders with members of various industries to explore their futures from four perspectives: crises, value chains, networks, temporalities. The content of scenarios was designed from prospective stakeholders' acts engaging industries in climate change adaptation, and to be ruled and challenged over time together with questioning stakeholders' capacities to act. Results stress on the process perspective the interest for a foresight collaborative process between different industries rather than focusing on a specific one to share experiences. On the content one, this participatory work beyond business silos produced community-based engagement scenarios empowering disempowered or supporting role stakeholders.

4 - Exploring the concept of plausibility in the development of future scenarios

Frances O'Brien, Eleanor Reynolds, Maureen Meadows

Scenarios are stories about alternative possible futures which capture key uncertainties. A key concept in the development and presentation of scenarios is that of plausibility. This paper is organised into three sections. First, we offer reflections on how plausibility has been defined and operationalised within the literature. Second, we reflect on experiences of students working with scenarios and how they have explored the plausibility of scenarios developed as part of an assessed participative exercise. Third, we reflect on how the concept was operationalised in a recent application of scenario planning that supported strategic conversations amongst a group of museums during the

Covid19 pandemic. We end by drawing together our reflections and comment on their relevance for the practice of scenario development.

1 - On the interplay between data and decisions in discrete location problems

Hannah Bakker

The capacitated facility location problem (CFLP) is a core problem in location science. While the influence of the spatial patterns underlying a CFLP problem instance is widely acknowledged, their relationship with the optimal decisions is insufficiently explored. I will give an overview of my research on how spatial relationships between candidates and customers can be accessed through pattern recognition. With the help of an illustrative example, I demonstrate that these relationships affect the stability of solutions, the performance of solution algorithms, and even indicate the potential added value of moving to a more comprehensive problem formulation including further aspects like time or uncertainty. I outline how explicitly acknowledging these relationships bears significant potential for algorithm selection, algorithm development, and data-driven modeling.

2 - Managing Manufacturer Encroachment and Product Conflicts in a Closed-Loop Supply Chain: The Case of Information Asymmetry

Qin Zhou

Implementation of direct channels allows manufacturers to distribute new and remanufactured products through separate channels. This prompts careful consideration of which products to channel directly. In the production of remanufactured products, manufacturers often delegate the collection of used products to retailers. However, the efficiency of this collection process is typically private information, known only to manufacturers through its probability distribution. To explore the impact of information asymmetry on manufacturers' decisions, we constructed a dual-channel closed-loop supply chain model involving a manufacturer and a retailer where the manufacturer can design non-linear contracts, incentivizing the retailer to choose contracts that align with its capabilities, ultimately maximizing the manufacturer's profit. The study findings indicate that when the retailer exhibits high collection efficiency and remanufacturing costs are low, information asymmetry can distort the production quantities of new and remanufactured products. Manufacturer encroachment consistently proves advantageous, mitigating the negative effects of information asymmetry on product output and consumer surplus. It also raises the entry barrier for manufacturers contemplating remanufacturing. Additionally, a cost threshold for remanufacturing is identified, creating a divergence in how information asymmetry influences manufacturers' profits under various contract types.

3 - Complexities in high-tech manufacturing

Mirjam Meijer

High-tech manufacturers produce and assemble state-of-the-art products that consist of many complex components sourced from dozens of suppliers. Examples are the production of lithography machines by ASML or the production of aircraft by Boeing or Airbus. To assemble these high-tech end-products and deliver them to the customers, it is important that all required components are available as shortage of a single component may lead to costly delivery delays of the end-product and large inventories of other components. This requires sufficient capacity of the suppliers, who face their own trade-offs and may be hesitant to invest in too much capacity, or high inventory buffers, which

is also costly and increases the risk of obsolescence. In this talk, we will discuss such challenges, resulting trade-offs and their effects on optimizing the decisions.

4 - Leveraging Operations Management to Improve Access to Justice: A Research Agenda on Court Congestion

Shany Azaria

Court congestion is a pressing issue worldwide, affecting social welfare, economic development, and access to justice. This research agenda aims to address the challenges posed by court congestion through the lens of operations management. By employing empirical research, the application of theoretical frameworks, and data-driven methodologies, we seek to unravel the operational complexities and identify solutions to improve judicial system efficiency. Utilizing comprehensive datasets from the US Federal District Courts and the Israeli court system, this project employs a variety of techniques including natural language processing, artificial intelligence, and econometrics to analyze the effects of judicial congestion. Our approach leverages operations management tools, process-mining, and queue-mining to propose and evaluate interventions designed to reduce congestion and enhance system performance. The significance of this research lies in its potential to contribute to both the operations management field and societal welfare by offering insights and interventions that facilitate access to justice. By bridging theoretical innovation and practical solutions, this research aims to forge new paths in operations management and social impact.

Humanitarian Aid

Stream: Secure & Sustainable Food Supply
Invited session

Chair: Joris Wagenaar

1 - A matheuristic for the foodbank routing problem

Istenc Tarhan, Ceyda Oguz

Zero Hunger, a UN Sustainable Development Goal, aims for a hunger-free world while also targeting the reduction of food waste. Supermarkets are major contributors to food waste due to surplus from wholesale operations. Food banks play a vital role in salvaging and distributing surplus food to the needy, but they often face budget constraints and therefore lack of transportation means. This study proposes collaboration among food banks to address these challenges, where those with transport capabilities assist smaller ones. This collaborative effort introduces a new logistical challenge, characterized by the perishable nature of foods and the selective nature of the problem—determining which supermarkets to visit, which foods to collect from visited supermarkets, which food banks to visit to deliver collected foods. This multi-objective problem aims to optimize the amount of food delivered to foodbanks as well as their fair allocation, and to minimize costs and carbon emissions associated with transportation operations. To solve this problem, we introduce a matheuristic algorithm. This algorithm iteratively solves single-vehicle subproblems and employs a master model to produce a solution for the original multi-vehicle problem, leveraging single-vehicle solutions. Computational experiments conducted with both real-life and synthetic data demonstrate the efficacy of this proposed methodology. The work described in this study is supported in part by TUBITAK 1001 grant 121M585.

2 - Preventing malnutrition: quantitative tools for decision-making in optimizing diets and interventions for regions with limited economic access to adequate diets

Marc Juanpera, Pol Gil-Figuerola, Melissa Koenen, Sabrina Kuri, Claudia Damu, Laia Ferrer-Martí

More than 3100 million people (42%) could not afford a healthy diet in 2021, resulting in malnutrition and immediate and long-term health issues. Regional and national governments can promote nutrition policies (e.g., subsidizing nutrient-rich products), often targeting vulnerable population groups (e.g., children under 5, pregnant or lactating women). Due to the different nutritional composition of the food items and the varying nutritional requirements of the population (with age and sex), selecting the overall best policy is not straightforward. This study combines bi-objective optimization and multi-criteria assessments, providing comprehensive quantitative tools to assist in defining diets and assessing the impact of interventions on the nutrition intake of the population. It defines three stages: 1) a bi-objective optimization model to compute Pareto-optimal solutions for daily diets concerning cost and nutritional adequacy; 2) a multi-criteria procedure to determine the best diet for each population group, considering economic, social (equity), and environmental factors (water and CO2 footprint); 3) a multi-criteria procedure to evaluate interventions and select the most effective based on economic, social, and institutional factors (promoting local economy). Regions of Cambodia experiencing barriers to adequate dietary access are selected as a case study. Results can aid decision-makers in identifying diets and interventions to improve the nutrition of the population.

3 - Mapping post-disaster infrastructure using GPS data from relief vehicles

Polle Dankers, Joris Wagenaar, Hein Fleuren

After a disaster strikes, relief goods need to be delivered to the beneficiaries as efficient as possible. However, a disaster may destroy a part of the infrastructure. Knowledge about the state of infrastructure is essential to aid organizations in efficient routing. To map the state of the infrastructure, we estimate a distribution of the maximum speed one can drive on edges using GPS trajectories from relief vehicles, which are currently simulated.

This distribution is estimated in three ways: • For frequently driven edges, we only use their own GPS data. • For seldomly driven edges, we also use their own GPS data. Additionally, we use a measure on the likelihood of the edge being deliberately avoided after the disaster. We check how often it should have been part of optimized routes based on the pre-disaster infrastructure, while it is not in the driven trajectories. If the edge is likely avoided, we estimate the proportion of delay incurred on the edge, assuming that the pre-disaster route would be chosen if not damaged. • Undriven edges in pre-disaster optimized routes are also predicted with avoidance estimation. Undriven edges which are not in pre-disaster routes are labeled unpredictable.

The approach can be used in a static setting, predicting the state of infrastructure only once. It can be extended to a dynamic version where the predictions from the prior time period are used as infrastructure during the next period's trajectory generation.

4 - A robust approach to food aid supply chains

Joris Wagenaar

One of the great challenges in reaching zero hunger is to secure the availability of sufficient nourishment in the worst of times such as humanitarian emergencies. Food aid operations during a humanitarian emergency are typically subject to a high level of uncertainty. We develop a novel robust optimization model for food aid operations during a humanitarian emergency, where we include uncertainty in the procurement prices, which is one of the primary sources of uncertainty in practice. Due to the multi-period and dynamic nature of food aid operations, we extend this robust optimization model to an adaptive robust optimization model. Moreover, we analyse a folding horizon approach for the nominal, robust, and adaptive robust optimization models in which decisions can be altered in later time periods. We compare the different approaches based on a food operations case in Syria. We show that the (adaptive) robust optimization approach outperforms the nominal approach in the non-folding horizon case, while the nominal approach performs best in the folding horizon case. Consequently, in case decisions have to be made early on, we show that applying robust optimization to food aid operations can make a difference. However, in case small adaptations can be made to the decisions taken in later time periods, then food aid operations can use a relatively simple approach in practice and apply a folding horizon approach each month to optimize decisions.

1 - Admission and early discharge policies for ICU patients during times of intense demand in a pandemic

Dong Li, Li Ding, Navid Izady, Richard Wood, Christos Vasilakis

This study addresses the limitations of existing intensive care unit (ICU) triage policies by developing an algorithmic model for admissions/discharges during times of intense demand in a pandemic. Embracing a multi-value ethical framework, our model aims to maximize aggregated benefits while considering the principles of fairness. The proposed model accounts for the illness pathways of individual patients, the overall mixture of patient profiles, and the uncertainty in the number of future patients. We introduce a cost for early discharges to account for psychological and ethical complexity and build a discrete time Markov Chain from actual patient data to capture disease progression of ICU patients. We conduct a survey among ICU physicians to estimate short-term benefits of intensive care. The problem is formulated as a discrete Markov Decision Process. To address the computational complexity, we relax the capacity constraint and formulate an alternative problem for each single patient. We characterise the optimal admission and discharge policy for individual patients, which allow us to develop a heuristic policy for the original problem. The performance of the proposed policy and alternative benchmarks are evaluated in a comprehensive simulation study. Our results reveal the scale of impact possible through appropriate clinical decision-making regarding patient admission and discharges, demonstrating potential benefits in both lives and life-years saved.

2 - Contagion-aware patient choice: managing multichannel healthcare delivery during a pandemic

Elif Karul

We consider the multichannel healthcare delivery problem during a pandemic and explore capacity allocation and pricing decisions for the in-person and telemedicine channels. We propose a model that explicitly considers patient choices between the channels, including the fear of contracting the disease in an in-person visit. The effect of contagion on the patient's channel choice is endogenous. Choices drive in-person volume which in turn drives the contagion effect. We show that in equilibrium when the potential demand increases linearly, the in-person demand increases logarithmically due to the endogenous contagion effect. This explains the documented revenue losses of healthcare systems during the COVID-19 pandemic and underlines the tele-channel's importance as a leading revenue source. Under optimal pricing, we find a positive price gap between the channels that increases in contagion awareness of the patients, a behavioral parameter in the model. In comparison with a revenue-maximizing healthcare provider that prefers the higher-priced in-person channel, when physician infection is also considered, a social planner is shown to allocate more capacity to telemedicine thereby protecting physicians. Modulating channel choice by increasing patients' contagion awareness can be beneficial for both revenue and welfare. Even partial awareness can go a long way in compensating the revenue losses, despite the negative impact of contagion awareness on total demand in equilibrium.

3 - What is the price for flow-sizing critical care resources with fairness?

Nikolaos Rachaniotis, Thomas Dasaklis, Platon Tiniotis

The term "flow-sizing" in health systems refers to the strategic operations management of critical care resources according to the dynamic patients' flow, adapting the resources' availability to the fluctuating needs. The necessity of a comprehensive, quantitative approach to flow-sizing has become particularly relevant after the latest COVID-19 pandemic and planning for adequate capacity to confront the next critical care crisis is urgent. This research work attempts to develop a utility function that incorporates the major critical care capacity metrics. The objective is to match capacity and critical care demand to ensure that all patients receive appropriate and fair care, as well as capturing this fairness' price. The vertical and horizontal integration capability of critical care delivery (mainly ICUs) for healthcare organizations, and its flow-sizing process in a fast and cost-effective manner during normal, strain and surge conditions, are taken into consideration. As a case study, the performance of the Hellenic healthcare system in terms of providing critical care during COVID-19 pandemic is examined.

Acknowledgement: This work has been partly supported by the University of Piraeus Research Center.

4 - Enhancing Pandemic Evolution: A Simulation Modeling Study Utilizing German Multicenter Data to Unveil the Value of Federated Machine Learning

Stefan Kempter

The basic idea of Federated Machine Learning is to collect models rather than data centrally. We study the feasibility and the potential of the rather young research area, which has been proposed by Google in 2016, for digital Covid-19 diagnosis based on German multicenter data of 3,670 patients. Therefore, we compare Federated Machine Learning to traditional testing methods such as antigen or PCR (Polymerase chain reaction) tests on economical and operational dimensions. We aim to inform essential decisions regarding the choice of diagnostic methodology during the progression of a pandemic. Accordingly, we run a time dependent simulation for Federated Machine Learning to digitally diagnose Covid-19 and find a significant potential. The federated deep learning model with six clients and full access to all datapoints achieves an F1-score of 89.9 percent. For comparison, the centrally trained model reaches up to 92.5 percent. Our results highlight the potential of applying Federated Machine Learning to Covid-19 diagnosis. The study might therefore function as a benchmark for hospital managers to contribute to future research while maintaining governance of their data.

1 - Momentum Effects in Team Sports: Analysing the Interaction between Offence and Defence in the NBA

David Winkelmann, Rouven Michels

The phenomenon of momentum in sports has been explored in various studies; however, there is little evidence regarding the interplay between offence and defence. Using play-by-play data from NBA seasons 2015/16 to 2018/19, we investigate potential team-level momentum effects. Within state-space models, we first analyse offensive and defensive performances independently and, afterwards, integrate them into a joint framework. Our findings reveal the absence of significant momentum effects in the separated state processes. In contrast, we obtain a positive and significant momentum effect in the combined model. These results indicate that a successful defence performance affects the offence and vice versa. As such, it underlines the necessity of including characteristics such as the interaction between offence and defence for an accurate analysis of momentum in team sports.

2 - Optimizing IPL cricket 2023: selecting top batsmen and bowlers with the multi-MOORA method

Uttam Kumar Bera, Dipayan Bhowmik, Azharuddin Shaikh, Anirban Tarafdar, Pinki Majumder

In the context of procuring cricket players during an IPL auction, a comprehensive assessment of various elements becomes imperative, encompassing metrics such as batting average, strike rate, and total runs amassed for batsmen, alongside economy rates and wicket tallies for bowlers. The process of player selection inherently mirrors a Multi-Criteria Decision Making (MCDM) problem, wherein the challenge lies in reconciling conflicting objectives to identify the most suitable candidates. This paper undertakes an empirical investigation utilizing the multi-MOORA method, leveraging real-life data from the recent IPL 2023 season. By meticulously considering all pertinent attributes of players, we establish a prioritized ranking scheme. Moreover, we conduct a comparative analysis with established methodologies such as MOORA and WASPAS to discern their efficacy in this context, thereby shedding light on their respective strengths and weaknesses.

3 - Fast Laps and Fast Stats: A Scalable Spatial Model of Circuit Topographies and their Performance Impact for Constructor and Drivers in F1

Stephanie Kovalchik

Understanding how a car and driver will perform on a given circuit is a central concern of constructors in motorsport. Statistical modelling can be a powerful tool for analysing the interplay between car, driver and circuit features through partial pooling across fine-grained circuit topographies. Telemetry data provides a rich set of inputs for spatial models, yet, the size of the data requires highly scalable methods. We have developed a framework to approximate a Bayesian hierarchical Gaussian process that allows the estimation of latent circuit topographies and their interaction with car and driver at scale. Our fast approach to modelling the spatial characteristics of circuits is applied to the performance outcomes for all races of the 2023 Formula 1 season. Our results demonstrate the predictive and descriptive utility of the framework as it can predict results for new circuits within season and find topographical features where car and/or driver are expected to have the greatest and least advantage over the field.

2 - Energy consumption decomposition analysis in developing countries with specific reference to India

Jinal Parikh, Gerhard-Wilhelm Weber

The International Energy Agency (IEA) recently revealed that - "Strong GDP growth and a weak monsoon drove up India's energy-related carbon emissions by around 190 million tonnes in 2023, though the country's per capita emissions remain far below the global average". Given its target growth rate of 9% of reaching an economy of \$5 trillion by 2024-25, it is an immense challenge for India to meet the growth target while keeping its GHG emissions under control. While SDGs 7 & 13 call for affordable and clean energy & climate action respectively by 2030, improving energy efficiency while keeping the GHG emissions under control could be one of the key paths to address the issues of energy security, climate change and economic stability for India. Further, India is characterized by considerable differences in energy efficiency in different regions resulting from differences in their economic and demographic trends, resource availability and industrial profiles. Given this background, this paper aims to: 1) identify the potential sources which influence India's GHG emissions at regional level 2) explore various methods of decomposition analysis viz. IDA, SDA and PDA and apply the most appropriate amongst them to investigate potential sources on GHG emission changes 3) to extend the authors' research presented at IFORS-2023 by performing decomposition analysis with GDP as the desirable output and GHG emissions as the undesirable output respectively.

3 - Non-linear Task Valuation in resource allocation problems

Wen-Chih Chen

Allocating resources to various tasks is a critical decision in practices. One of the difficulties arises from the intangible nature of task values or importance, making it challenging for decision makers to express them explicitly. Additionally, the value is nonlinearly linked to the level of allocated resources. This work proposes a method to estimate the non-linear value function by the historical decisions. Simulated studies are used to demonstrate the effectiveness of the proposed method.

1 - Recent development on the Markov decision and semi-Markov decision processes

Olabode Adewoye

Our world is bedeviled with uncertainty and complexity. Markov models originated by A.A. Markov and further extended R.A. Howard and later, many other contributors, formulate, analyze, and evaluate simple and advanced models to solve the world's dynamic and complex problems ranging from genetics to robotic engineering and maintenance problems and sustainable developments. This work surveys recent developments in Markov decision processes (MDP) as well as provides insight into how MDP and Semi-Markov Decision Processes can be applied to a variety of problems. The finding shows that any practical problem on complexity and uncertainty can at least be modeled as a Markov model, provided we can break the problem into states, establish the transition probabilities, the rewards structure, and the optimization criteria are known.

1 - Unit Commitment problem with uncertain demand and renewable energy availability

Cristian Aguayo, Bernard Fortz

Energy generation is an area where four of the many problems facing humanity today - the energy crisis, climate change, scarcity of natural resources and global warming - interact in a vicious circle. In this scenario, it is not surprising that governments around the world are reviewing their energy policies. Agents such as Renewable Energy Sources (RES) and Local Energy Communities (LEC) can play a fundamental role in the energy transition. However, the optimization of operational costs continues to be a relevant factor. The Unit Commitment (UC) problem is one of the classical approaches to optimize these costs. This problem involves decisions related to the schedule of generating units as well as the power they must produce in order to meet the total power demand, where the last one can be deterministic or uncertain. By integrating RES, a new source of uncertainty is added to the problem. In this work, various formulations for the UC problem with uncertainty are presented and solved using benchmark data.

2 - Mixed-integer non-linear programming approach for identifying parameters inconsistencies in load flow calculations

Martin Debouté, Pierre Arvy

For several decades, electrical networks have experienced continuous expansion in size and scale, facilitating the transmission of electrical power from sources to end-users. The growing complexity of these networks necessitates the use of tools like Load Flow calculations, which are crucial for power systems engineering, playing a critical role in ensuring grid reliability and efficiency. This numerical analysis of electric power within interconnected systems determines steady-state voltages, currents, and power flows across network components. Given the significance of LF calculations, the power systems community has invested substantial efforts in enhancing the convergence of the methods used to solve them. Despite these efforts, real-world scenarios often involve imperfect or erroneous network parameters, leading to challenging convergence issues for existing methods. The physical problem studied may be mathematically infeasible due to complex inconsistencies in the parameters. This research project explores a novel approach centered around Mixed-Integer Non-Linear Programming to detect inconsistencies or errors in the parameters of a power network. The study extends with the implementation of an open-source tool using the AMPL modeling language, and conducts a solution to the problem using the commercial solver Artelys Knitro. Finally, the tool has been tested to ensure that it successfully identifies inconsistencies in a real-world use case within an acceptable time.

3 - Modeling the interaction between local energy management and a global electric system

Kallia Charron, Frederic Lantz

Local energy management (LEM) addresses local stakes and thus a LEM strategy does not necessarily align with the aim of a centralized electric system. Yet, if spread widely, it can affect the global load curve and therefore the global electric system (GES) and the price associated. In addition, the investment decision into a LEM solution and oftentimes the management strategy itself are highly dependent on the global electricity price and the accuracy of its prediction. Hence, what would be the impact of a LEM solution adoption - by a significant number of consumers, referred to as "local consumers" - on its own profitability through the effect it can have on the global price? This paper aims at modeling the interaction between LEM and a GES. To do so, we propose a two-level equilibrium optimization model. One level models the impact of implementing a LEM solution for a "local consumers" on their aggregated load curve. The second level models the variation in the global electricity price resulting from the shift of the global load curve induced by those local consumers. The price being both a decision parameter for the LEM in the first level and the output of the second, the optimization purpose is to find the equilibrium. This paper then presents the results of the model for several LEM solutions such as demand response, residential photovoltaic self-consumption and management of electric vehicle charging, using aggregated simulated data for the consumption.

4 - Enhancing N-PERT Solar Cells under the Atacama Desert Solar Spectrum

Benjamin Ivorra, Pablo Ferrada, Gabriel López Rodríguez, Angel Manuel Ramos

In the Atacama Desert, solar radiation deviates from the global standard, boasting high irradiation levels with intense ultraviolet content. Given the spectral dependence of photovoltaic (PV) technologies, optimizing PV devices mandates consideration of local conditions and technology type. Solar cells are typically optimized for standard conditions, but our study focused on adapting them for Atacama's unique spectrum. We optimized an n-type bifacial passivated emitter and rear totally diffused solar cell (n-PERT) by adjusting geometrical and doping parameters using a hybrid genetic algorithm. Six parameters—cell and emitter thicknesses, back surface field thickness, and doping concentrations—were optimized for both Atacama spectrum (AM 1.08) and standard conditions (AM 1.5). Validating our model, we found the computed and experimental efficiencies to differ by less than 1% under standard conditions, affirming accuracy. Our optimization revealed the

necessity of tailored configurations and doping for Atacama deployment. Reducing layer thicknesses and increasing doping led to a 5.4% efficiency boost under AM 1.08. Finally, we emphasize the potential impact of metallization and the feasibility of thinning the emitter and back surface field, opening avenues for enhanced PV technology in extreme environments.

1 - Lessons learned on the OR way

Elise del Rosario

This is a personal sharing of lessons learned from someone who was deeply involved in Operations Research - in a corporate setting, as a national society organizer, an international OR group leader, a consultant in supply chain and a pro-bono government consultant. There were many lessons learned along the way that the speaker hopes will benefit others.

2 - The origin of the Branch-and-Bound Method

Janny Leung

In 1960, under the simple title "An automatic method of solving discrete programming problem", the method for solving mixed-integer-programming problems was introduced. This Branch-and-Bound framework, with enhancements, remains at the core of discrete optimization software to this day, more than 60 years later. We will discuss the many pioneering ideas of this paper, and also the two women pioneers of operational research, Ailsa Land and Alison Doig Harcourt, who co-authored this landmark paper.

3 - The "Subject to" (s.t.) podcast: sharing experiences, gaining insights

Anand Subramanian

The "Subject to" (s.t.) podcast offers a series of informal conversations with relevant figures in the fields of Operational Research, Combinatorial Optimization and Logistics, and they are hosted by Anand Subramanian, an Associate Professor at Universidade Federal da Paraíba (UFPB), Brazil. The episodes can be accessed on YouTube ([https://www.youtube.com/@ Subjectto_](https://www.youtube.com/@Subjectto_)), as well as various podcast platforms such as Spotify, Google, Apple, etc. The goal of the s.t. podcast is to inspire the next generation of operation researchers by means of informal yet in-depth conversations with great names in the field of OR in the form of oral history. Moreover, in addition to providing technical discussions, the podcast attempts to portray the human side of the guests, otherwise generally known only for their work, by walking through their professional and personal life stories, and presenting a snapshot of their career within the relevant historical OR context. The episodes often touch on societal elements such as gender and diversity issues, and other pertinent nontechnical topics like the best strategies to better promote the field. So far, there have been more than 85 episodes with many important names from 28 different nationalities spread across 22 countries all over the world. This contribution aims to share some insights gained from experiences of distinguished personalities, predominantly from academia, but also from the industry.

4 - The sustainability of operations - past, present, future

Joel Joris Van de Klundert

Human operations, whether in business, at home, or otherwise, are causing a transgression of the boundaries of a safe and just operating space for planet Earth and humankind. Developments in operations that have steadily grown over the long course of history, and which have especially gained momentum since the uptake of fossil fuel powered machines in the recent and on-going industrial revolutions, now threaten to cause irreversible damage to ecosystems and society. The present situation calls for new perspectives and understanding of operations and operations research that enable to change the course of development and for operations to provide sustainable solutions for the planet and humankind.

In this talk we firstly reflect on the history of operations while explicitly reflecting on its environmental and social sustainability and on the corresponding development of operations research, roughly from the Big Bang onwards. Next we reflect on the (un)sustainability of today's operations and reflect on operations research contributions (being) made.

The on going 4th industrial revolution, which depends so extensively on analytics and data science, promises to change the way humankind lives and works, the way we operate, once again. Hence it provides a window of opportunity for operations researchers to learn from the past and aim to contribute to creating sustainable operations for humankind and planet Earth. We review the state of the art on contributions of the fourth industrial revolution for sustainable operations and highlight priorities for future sustainable operations research.

Infectious diseases and pandemics

Stream: OR in Humanitarian Operations (HOpe)

Invited session

Chair: [Laura Heuser](#)

1 - Operationalising Policy: Distributing Vaccines in a Pandemic/Epidemic

Foteini Stavropoulou, Sarah Schiffing, Liz Breen

In the response to the COVID-19 pandemic, vaccine distribution was initially characterised by scarcity with limited production capacity and high demand. While policy decisions to prioritise certain patient groups over others have been widely discussed, this paper focuses on providing a user-friendly and adaptable approach to align vaccine allocation decisions and distribution plans with the government-imposed prioritisation policies. We introduce the Vaccine Distribution Problem, and we propose four mathematical formulations relating to the Vehicle Routing Problem with profits, a concept that has not been adopted within humanitarian or healthcare supply chain applications. This problem aims to allocate the available vaccine supplies to a set of predefined vaccination sites fairly, following a given prioritization policy, while designing the corresponding set of vehicle routes that maximize the total collected profit. We incorporate split deliveries and incomplete service as well as a profit adjustment mechanism to ensure fairness in the vaccine allocation decisions and maximise resources utilisation. To validate and evaluate our approach, we created a real-world case study based on Liverpool, an English city that was affected severely by COVID-19, using only publicly available data.

2 - Analysing the Potential of Mobile Laboratories To Prevent Outbreaks of Infectious Diseases

Mette Wagenvoort, Iman Parsa, Luk Van Wassenhove

Infectious diseases are a significant contributor to death rates. Furthermore, they have a significant effect on the economy due to increased public health costs and loss of income. Earlier identification of

pathogens through testing can help achieve outbreak prevention. However, poor rural areas have limited access to health facilities, which causes a large delay between the emergence and the identification of a disease. Mobile laboratories can help identify outbreaks in such areas as they allow for fast preventive testing at different locations. However, the benefits of a mobile laboratory might not outweigh the benefits obtained from directly investing the money in the local health facilities. Therefore, we analyse the trade-off between sending mobile laboratories and investing in local health facilities such that outbreaks are prevented.

3 - Manufacturing and Procurement Strategies of Relief Supplies Considering Disruption Risk in Response to COVID-19

Yanfang Ai, Afshin Mansouri, Jun Tian

Confronted with the urgent demand for medical supplies in COVID-19, governments encouraged manufacturers to invest efforts in expanding and transitioning their production to bolster the supply capacity of relief supplies. However, the limited supply capacity and the risk of interruption in the upstream supply chain of critical raw materials hinder the expansion of manufacturers' capacity. We address this challenge within a relief supply chain consisting of a supplier and two competing manufacturers under various government subsidy strategies. In this study, we develop a game-theoretic model where an incumbent and an entrant manufacturer engage in two-dimensional competition involving production investment efforts and sales volume. We examine three scenarios: (1) no subsidy, (2) per-unit sales subsidy, and (3) per-unit price subsidy to understand the effectiveness of subsidy strategies in different contexts. Furthermore, we evaluate the stability performance of the subsidies from an evolutionary game theoretical perspective. We find that when the entrant manufacturer has a high level of investment efficiency, they prefer the per-unit sales subsidy over the price subsidy strategy. Additionally, government subsidies can promote production quantities, investment efforts, and social benefits for all stakeholders. To demonstrate the practicality of our results, we apply them to the case of China's response to COVID-19 and compare it with strategies adopted by the UK government.

4 - Influence of Inventory Policies on Epidemic Progression in Networked Metapopulations

Laura Heuser, Stephan Wagner

Infectious diseases cause more than 25% of global deaths, but appropriate treatment can reduce the impact of epidemics. To account for treatment availability, we develop a networked metapopulation Susceptible-Exposed-Infected-Treatment-Recovered (SEITR) model that depends on supply chain inventory policies. The focus of this paper is on inventory policies during preparation (Prepositioning) and response (Reorder Point, Ordering, Inventory Rationing, and Delivery Scheduling) to the epidemic. Our approach involves Python-based simulations with customized Latin Hypercube sampling to sample parameter-policy combinations and Monte Carlo techniques to account for randomness in the model. Using the case of Uganda's three-tier medical supply chain, we analyze the impact of different parameter-policy combinations on epidemic outbreaks. The analysis quantifies this impact through key performance indicators (KPIs) from epidemics and supply chains, including final epidemic size, treatment ratio, outbreak duration, stockouts, service levels, and inventory left over. We will identify optimal policy-parameter combinations that improve responses to future epidemic outbreaks within specific categories of epidemics. We aim to provide actionable insights to enhance Uganda's national inventory policy for public health emergencies while contributing to the literature by providing insights about the most influential policies and parameters.

■ WB-22

Capacity expansion planning for energy systems

Stream: Energy Management

Invited session

Chair: Beste Akbas

1 - Models for electricity capacity expansion with demand uncertainty and a carbon budget

Beste Akbas, Eddie Anderson, Heikki Peura

Energy capacity planning faces numerous uncertainties, especially regarding future demand and changes in generation costs. The development of new technologies has challenged previous assumptions about the affordability of renewable energy sources. As a result, the changing cost dynamics disrupt the traditional patterns, leading to significant impacts on expansion decisions and the future composition of the generation portfolio, influenced by the shifting dynamics between renewables and conventional sources. Additionally, the construction of new electricity generation facilities powered by gas or nuclear typically entails lengthy construction periods, with operational lifespans expected to extend beyond 15 years. Nevertheless, capacity expansion extends beyond long-term projects. Short-term strategies, including extending the lifespan of existing generation capacity that would otherwise be retired, and implementing demand response initiatives, have significant influence over the overall capacity landscape. In this study, we examine the socially optimal capacity expansion decisions, taking into account future carbon targets, demand uncertainty, and the integration of long-term and short-term generators.

2 - Multiperiod Planning Model for Long-Term Expansion of Energy Distribution Systems Considering Advanced Reliability Topics

Alejandra Tabares, Julian Andrés Infante, Ana Maria Montes

In energy distribution networks, adequate investment planning is crucial not only for meeting the demands of established load points within the network but also for maintaining specific reliability standards. These two objectives, which involve meeting the demand economically and ensuring adequate service reliability levels, are highly dependent on the investments made in the electrical network. Therefore, this paper presents a mathematical model that incorporates both criteria to determine investment decisions in distribution networks. The developed model incorporates various types of investments, commonly found in long-term projects, such as investments in substations and circuits, which are evaluated over multiple investment periods. Moreover, a set of constraints is utilized to account for potential outage scenarios in the networks and assess the robustness of the investments against them; this includes considering circuit breakers as essential network structures for conducting network reconfigurations that minimize the number of users affected by outages. As a result, cost benefits were observed when incorporating decisions regarding the investment in circuit breakers, circuits, substations, and necessary upgrades due to the increase in network demand. The final study was conducted using a 14-node and a 27-node model.

3 - Multi energy mixed integer linear programming model for generation and network expansion planning with coupled electricity and heat sectors considering renewable sources

Anibal Baradei, Matteo Pozzi, Angelo Gordini, Aldo Bischi

Multi energy systems optimal planning main challenge is the equilibrium between model accuracy and computational feasibility. This is due to the need of large-scale, nationwide, generation and transmission expansion model that incorporates aspects such as optimal units and storage scheduling, space constraints, and renewable energy sources availability. Furthermore, the deep decarbonization needs of the future energy systems implies to have coupled energy infrastructures, e.g.

electric, heat, gas, and long duration energy storage including all the possible interactions between them through multi year periods, yields an increasing model complexity. It is modeled as a mixed integer linear problem and aims to include all the key features of state-of-the-art models obtainable from a linear formulation. The objective function is the minimization of the overall system cost, and it includes investment, maintenance, network expansion, transmission hourly prices, energy regulations, and fuel prices.

The model has been implemented in Python language using Gurobi solver with an hourly time step. It can tackle in few minutes more than a year depending on the problem size: a yearly instance of 200 nodes yielded about 320 million continuous and tens of binary variables. The model flexibility enabled to run various sensitivity analyses to tackle uncertainty considering fuel availability, natural resources, different technologies, regulations, load profiles and time evolution.

4 - Renewable Hydrogen Supply –A Novel Global Dataset on Resource Potential and Hydrogen Production Optimization.

Age van der Mei, Audun Botterud

While data for policy-making and planning is available for solar and wind resources, this is lacking for renewable hydrogen. Even as hydrogen is seen as an important part of the energy transition away from fossil fuels, it is unclear where, and at what costs hydrogen could be produced at scale and supplied into the global energy system. The lack of available data creates challenges for planning and investment decisions. We present a database that provides techno-economic data on hydrogen production from solar and wind and describes global technological and economic potential. The database starts from 10 years of ERA5 reanalysis data and adds technology performance data to enable optimization of renewable hydrogen supply at the global level. We illustrate potential use of the database by optimising the installed capacity for solar-PV, wind turbines, lithium-ion batteries, and electrolyzers to meet future hydrogen demand. The data provides a timely and valuable view of the supply side of renewable hydrogen aiming to underpin renewable energy and hydrogen policy considerations.

Wednesday, 10:30-12:00 - Room: 82 (building: 116)

Recycling

Stream: Circular Economy, Remanufacturing and Recycling

Invited session

Chair: Müge Çakan

1 - An agent-based approach to exploring consumer behavior and the effectiveness of persuasion strategies in waste separation and recycling in China

Yan Xu, Xinzhu Wu

Consumer behavior in terms of waste separation and recycling (WSR) is extremely important to achieve the goal of "zero-waste city" and circular economy. However, there is a discrepancy between consumers' willingness to participate in waste separation and their actual behavior in China. The government's persuasion strategies have limited impact on changing WSR behavior. We argue that the strategies need to collectively change WSR behavior through their influence on the motivation and ability (M/A) of all consumers to achieve extensive public participation. Therefore, we propose a novel agent-based approach that integrates a psychological behavioral model and a simulation model to analyze WSR behavior and the effectiveness of persuasion strategies. A behavioral model based on the Fogg behavioral model is developed to investigate the M/A elements that influence WSR behavior. A multi-agent model is developed to analyze WSR behavior by considering the interactions between individual consumers and the environmental and

peer pressures. By simulating the changes in WSR behavior under different strategy implementation scenarios, we find that consumers' M/A are constantly changing due to their interactivity, and the public participation rate is significantly higher when diverse strategies are implemented that encompass all M/A elements. Our proposed approach and empirical results contribute to the research and implementation of waste management and low-carbon consumer behavior.

2 - Life Cycle Assessment of Different options for Mixed Industrial Textile Recycling

Lorena Espinoza, Andrea Espinoza, Óscar C. Vásquez

The \$882 billion textile trade in 2021 raises environmental concerns, emphasizing the importance of promoting a circular economy for sustainable textiles. As a result, policies must prioritize textile recycling, especially in developing countries, as well as information sharing across the value chain. Thus, the purpose of this study was to investigate the potential environmental benefits of two industrial recycling processes for mixed textile residues. We conducted a life cycle assessment using the ReCiPe method at the midpoint and endpoint levels, with a focus on generating significant data availability and a broader assessment than existing literature to support decision-making related to textile residue recycling. The results of the textile residue recycling process to obtain stripes (R1) and replace sawdust to fill pushing balls demonstrate that it would produce environmental benefits regardless of location in several midpoint categories. In terms of endpoint results, the DALY savings are primarily due to avoiding final disposal, while the savings in ecosystem impacts are generated by avoiding landfill and sawdust production. In the recycling process to obtain recycled yarn and fill (R2), endpoint results show that the DALYs of all avoided processes are 1.5 times those of all R2 recycling processes, owing primarily to the avoidance of virgin yarn production. Thus, both recycling methods are recommended.

3 - Optimal recycling strategies of closed-loop power battery supply chain considering informal recycling channels

Songsong Liu, Feiyu Jin

The early electric vehicle power batteries have entered the retirement outbreak period in China. Although vehicle manufacturer is responsible for power battery recycling as required by policy, informal recycling channel is disrupting the normal order of recycling market. This work establishes three real situations based recycling modes in closed-loop power battery supply chain, consisting of manufacturer, retailer, cascade utilization enterprise, and informal recycling channel. Using Stackelberg game model, the optimal recycling strategies of closed-loop power battery supply chain under decentralized and centralized decision-making are obtained based on backward induction. Then, fair profit distribution schemes are designed for the three models under centralized decision-making. By validation through computational simulation, the results show that: (1) Under the decentralized decision-making, the profits of retailers and cascade utilization enterprises are severely squeezed by the informal recycling channel; (2) Under the centralized decision-making, informal recycling channel erodes retailers' profit by eroding their recycling volume, while the manufacturers' profit is not affected by the change in supply chain structure. This work enriches the theoretical literature by considering the informal recycling channel in the closed-loop power battery supply chain, and provides guidance to the formal recycling enterprises to compete with the informal recycling channels.

4 - Economic and Environmental Implications of Transferring Green Feedstock Credits

Müge Çakan, Moritz Fleischmann

Chemical recycling represents a new option for addressing challenges related to mixed and contaminated plastic waste. The chemical composition of the resulting feedstock is equivalent to that of virgin feedstock. Consequently, a product created from a blend of recycled and virgin feedstock exhibits the same quality as a product exclusively derived from virgin feedstock. Thus, the sole distinction between a "green" and a "brown" product lies in the claimed origin of the feedstock.

This opens the option to detach recycling credits from the physical product, allowing for credit transfer without the necessity for physical transport. However, this practice, known as multi-site attribution, is controversial. While industry claims attribution flexibility to be necessary for the economic viability of plastics recycling non-governmental organizations (NGOs) strongly oppose it and position it as greenwashing. Our research addresses this controversy and seeks to unravel the intricate dynamics of chemical recycling, attribution policies, and the evolving landscape of the recycling industry. Our aim is to assess the effects of various attribution policies on the environmental and economic performance of manufacturers through the application of an analytical model. Additionally, we aspire to provide policymakers with valuable insights into the ramifications of the transfer of recycling credits.

Carbon Regulation

Stream: Sustainable Supply Chains

Invited session

Chair: Fengfeng Xie

1 - Competitive retailers' sourcing strategies under Carbon Border Adjustment Mechanism

Fengfeng Xie

We investigate the influence of the newly implemented Carbon Border Adjustment Mechanism (CBAM) by the European Union on sustainable supply chain management. CBAM addresses the global disparity in carbon leakage due to divergent carbon taxation policies that vary across nations and regions. Given that CBAM is designed to prevent double taxation on carbon emissions, understanding its interaction with non-EU carbon regulation mechanisms, like cap and trade policies, is crucial. Our study primarily focuses on how the operational decisions of both EU and non-EU manufacturers are influenced by the interplay between the CBAM and cap and trade policy. Additionally, we aim to analyze how retailers within the EU determine their sourcing strategies, specifically, whether to source globally from non-EU manufacturers or opt for local sourcing within the EU. Our findings reveal that an increase in carbon emission permits allocated to non-EU manufacturers doesn't necessarily lead to a surge in profit. In fact, as additional permits are issued, the supply chain associated with non-EU manufacturers may encounter profitability dilemmas, impacting both the retailer and the non-EU manufacturer. We also find that when the CBAM fee is substantial, and the non-EU manufacturers are granted a large number of permits, retailers are more inclined towards local sourcing.

2 - Asymmetric Emission Regulations and Interventions of The Local Government

Taha Yasin Gürlesin, Özgen Karaer, Z. Pelin Bayindir

Carbon border adjustment can be described as a taxing mechanism where a carbon-regulated market taxes materials imported from unregulated regions. In this study, we analyze how a manufacturer exporting to two regions—one developed (and regulated) and one developing (and unregulated)—responds to CBAM imposed by the developed region. We study two models. The first is a base model in which the manufacturer sets prices for both regions. In the CBAM model, the manufacturer considers investing in green technology to reduce its unit emission and then sets prices for both regions, taking into account the carbon border tax. We also consider a local government that may offer incentives to the manufacturer to invest in green technology at the initial stage. We find that under some market conditions, neither the government's subsidy nor the carbon border tax causes a reduction in unit emission level.

3 - Who leads the way? buyer vs. supplier initiatives in supply chain carbon footprint reduction

Elif Kuscu, Özgen Karaer, Tarkan Tan

We study two supply chain models: (i) Buyer-Led Supplier Development and (ii) Supplier-Led Supplier Development, which are consisting of a buyer and a supplier. We analyze which player should initiate the carbon footprint reduction efforts in the supply chain under a scope 3 emission tax by using different levers. The supplier, as the producer, may invest to reduce the product carbon footprint. The buyer, as the downstream partner, may incentivize the supplier through supplier development initiatives. In the buyer-led model, the buyer offers a wholesale price premium rate contingent on improvement, and the supplier decides her carbon footprint reduction efforts accordingly. In the supplier-led model, the supplier offers sharing the carbon footprint reduction investment cost and the buyer decides the improvement level. We compare these two models and gain insights into their effectiveness under varying market conditions. Our results show that carbon footprint reduction is guaranteed if the supplier takes the lead, however, a wider range of improvement opportunities occur when the buyer initiates the reduction effort.

Topics in Integer Programming II

Stream: Combinatorial Optimization

Invited session

Chair: Mehmet Erol Kara

1 - Construction of value functions of integer programs with finite domain

Junlong Zhang

Value functions play a central role in integer programming duality, and they are also used to develop solution methods for stochastic integer programs, bilevel integer programs and robust optimization problems. We propose a column-by-column algorithm for constructing the value functions of integer programs with finite domain over the set of so-called level-set minimal vectors. The proposed algorithm starts with the first column and sequentially adds the rest columns one by one. The advantage is that no integer program needs to be solved in the algorithm and no dominated vectors are generated (only level-set minimal vectors are generated). Computational results on benchmark instances show that the proposed algorithm can reduce the computation time by up to three orders of magnitude compared with a state-of-the-art algorithm. We also extend the proposed algorithm to build value functions of integer programs with negative elements in the constraint matrix.

2 - An Exact Algorithm for the Euclidean k-Steiner Tree Problem

Jae Lee, Charl Ras, Marcus Brazil, Doreen Thomas

The classical minimum Steiner tree problem is an NP-hard problem that involves finding the shortest network spanning a set of terminals in the plane using additional points called Steiner points. In the minimum k-Steiner tree problem, the number of Steiner points is limited to some positive integer k. In a minimum Steiner tree, every Steiner point has degree 3, but the restriction on the number of Steiner points also allows degree-4 Steiner points to occur. This increases the number of topologies that are potentially optimal, which further increases the complexity of the problem.

To address the large number of topologies in the classical minimum Steiner tree problem, algorithms such as the GeoSteiner Algorithm implement various pruning tests. These pruning tests are based on the structural and geometric properties of a minimum Steiner tree and are used to discard the majority of sub-optimal topologies early on to deal with the large number of topologies. We take this approach and

create novel pruning tests that tackle topologies involving a degree-4 Steiner point. Hence, we create an algorithm that solves the minimum k-Steiner tree problem exactly, incorporating these new pruning tests in order to make it more efficient.

3 - On the box-total dual integrality of the perfect matching polytope

Francesco Pisanu, Roland Grappe, Mathieu Lacroix

A rational linear system is totally dual integral (TDI) if for every integer linear function, the associated dual problem has an integer optimal solution whenever the optimum is finite. Following the definition, TDI systems with integer right-hand sides characterize integer polyhedra. A TDI system is box-TDI if adding any rational bounds on the variables (i.e., boxes) preserves its TDIness. Classical examples of box-TDI systems are those involved in the Max Flow-Min Cut Theorem of Ford and Fulkerson. In general, box-TDI systems are systems that yield strong min-max relations.

In the early 80s, W.J. Cook proved that any TDI system describing a polyhedron allowing a box-TDI description is also box-TDI. Thus, box-TDIness is a geometrical property, and any polyhedron that can be described by a box-TDI system is called a box-TDI polyhedron.

Recently, a graph characterization of the box-TDIness of the matching polytope has been released. However, this characterization is too restrictive for the perfect matching polytope (PMP). In this talk, we highlight the differences between the two cases and provide insights for tackling the problem of characterizing the box-TDIness of the PMP. We also show that deciding whether the PMP of a graph is box-TDI is equivalent to testing the box-TDIness of its affine hull, which implies that "Recognizing whether the perfect matching polytope of a given graph is box-TDI can be done in polynomial time."

4 - A Mathematical model for routing of Industrial Inspection Robots

Mehmet Erol Kara, Aydin Sipahioglu, Ahmet Yazici

This study focuses on solving routing problem of industrial inspection robots by using mathematical model. Inspection robots are generally used to control. Especially in the production of bus, inspection of body in white of a bus has approximately 3000 subparts and all of them must be controlled. Since inspection time is important, routing of robot(s) is crucial. Robot arm starts from a starting point and moves another check point. When it finishes the control, traverses another check point until ensures all sub parts are controlled. However, in this process, determining the control points and calculating the shortest path distance between all pairs of nodes is important. Distance between check points should not be greater than sensor observation capabilities. Additionally, robot's movements are limited because of obstacles of body in white. Finally, a good route should be determined by visiting some check points. In this study the shortest path distances was calculated by using Floyd-Warshall algorithm and an integer linear mathematical model so as to minimize total traversing and inspection time is developed based on TSP. However, in this model, robot does not need to visit all check points in the network. The developed model was successfully validated on various test problems and the optimal solution could be obtained for small size problems. It was shown that a good solution can be obtained within 5 minutes for the problem having more than 1000 sub-parts with 170 nodes.

Combinatorial Optimization in Scheduling

Stream: Combinatorial Optimization

Invited session

Chair: Maciej Drozdowski

1 - Stochastic Quay Partitioning Problem

Maciej Drozdowski, Jakub Wawrzyniak, Eric Sanlaville, Frédéric Guinand, Yoann Pigné

In this presentation we consider dividing a quay of container terminal into berth segments so that quality of service for future ship arrivals is as good as possible. This problem will be referred to as a stochastic quay partitioning problem (SQPP). SQPP is defined by a ship traffic model (STM), arrival intensity, quay length and a set of admissible berth lengths. Alternative solutions are evaluated on various arrival scenarios generated for certain arrival intensity from a stochastic traffic model (the STM). Evaluation of an SQPP solution on one scenario is a problem of scheduling the arriving vessels on the berths, which is a classic berth allocation problem (BAP). In SQPP the sizes of BAP instances which must be solved by far exceed capabilities of the methods presented in the existing literature. Therefore, tailored portfolios of algorithms capable of solving very large BAP instances under limited runtime are used. Features of SQPP solutions are studied experimentally. We demonstrate, that partitioning a quay into equal length berths is not always the best approach. A set of algorithms to partition a quay is proposed and evaluated.

2 - Optimization of vehicle traffic in parking lots and access roads around the car plant

Grzegorz Pawlak

The practical traffic optimization model and the development of scenarios are considered to choose the most advantageous variant for the parking lot areas organization in the car factory plant. Traffic should run smoothly, i.e. without stoppages at the entrance/exit to the plant and without traffic jams in the plant zone, taking into account the effective flow of vehicles including the scheduling model in the multi-storey car parking. The micro logistic simulation model was developed, what if analysis and computational experiments performed.

3 - Affinity Aware Scheduling in Distributed Computing via Vector Bin Packing

Natalia Shakhlevich, Thomas Erlebach, Clément Mommessin, Renyu Yang, Xiaoyang Sun, Satish Kumar, Junqing Xiao, Jie Xu

The problem of allocating long-running applications (LRAs) to cloud resources can be modelled as vector bin packing (VBP) with additional compatibility constraints. In that problem, cloud compute nodes correspond to bins and LRAs to items. The multidimensional nature of the problem is associated with characteristics of bins and items, such as CPU cores, RAM, GPUs, etc. Planning resource allocation can be performed before LRA deployment and it is aimed at minimizing the number of nodes to which LRAs are allocated. In our study, we model affinity restrictions on LRA deployment. They are defined for pairs of LRAs which replicas can be jointly co-located to the same node, but with some limits, or for pairs of incompatible LRAs, which cannot be co-located. In our work, we explore a broad range of VBP heuristics capable of producing high quality solutions to the affinity-aware version of the problem and find a solution within acceptable time. The findings are supported by extensive computational experiments performed on the Alibaba Tianchi dataset.

4 - Integrated scheduling of work and training activities for a multi-skilled workforce

Azin Rashidipour, Broos Maenhout, Matthias Bogaert

This research proposes a comprehensive approach to skill-based staff scheduling and training, aiming to optimize workforce efficiency and minimize costs. The focus lies on efficiently assigning skilled workers to shifts within a defined time horizon and scheduling intermediate training sessions increasing the productivity of workers. The training of workers may encompass on-the-job or off-the-job training sessions. Importantly, both staff scheduling and training decisions are made concurrently during this phase, with training costs integrated with other expenses. The proposed algorithm encompasses a meta-heuristic procedure, which is initialised by creating baseline schedules without training, prioritizing task assignments and workforce availability. These initial schedules can be efficiently resolved using exact Mixed Integer Programming mathematical methods in a reasonable

computational time. The further optimisation aims to improve the costs via introducing training and is performed via dedicated local search operators and the combination of high-quality schedules following the principles of evolutionary processes.

Unraveling the Black Box: Advances in Model Explainability

*Stream: Mathematical Optimization for XAI
Invited session*

Chair: [Sandra Benítez-Peña](#)

1 - An in-processing and optimization-based method for a fair geographical regression

Pepa Ramirez Cobo

Fairness in Machine Learning is a prominent research area that, however has received little attention in the context of spatial or geographical data. This work is motivated by a real urban planning database that shows lack of equity in terms of access to green areas. On the basis of the geographically weighted regression (GWR), this work presents a regression model for predicting spatial responses in fair way. The parameters of the model, namely, the bandwidth parameter and the regression coefficients are estimated in two stages. First, the bandwidth is obtained from a jack-knife cross-validation approach. Second, the regression coefficients are the solutions of a quadratic optimization problem with linear inequality constraints modeling the unfairness of predicted responses. In order to deal with large datasets, an alternating block coordinate descent algorithm is suggested. The performance of the method is illustrated using an assortment of real datasets.

2 - Enhancing interpretability in Twin Support Vector Machines via variable selection

Sandra Benítez-Peña

Support Vector Machines (SVM) constitute a highly effective tool for solving binary classification problems. On the other hand, Twin Support Vector Machines (TWSVM) are based on the idea of constructing SVMs in pairs through generalized eigenvalues (GEP-SVM). These determine two hyperplanes not necessarily parallel by solving two problems similar to SVM but of smaller size. Consequently, the computational cost during the training phase is significantly reduced compared to traditional SVM. This requires solving two smaller quadratic programming problems (QPPs) that the one solved by the standard SVM. Moreover, many real-life problems, such as those related to fraud prediction and credit scoring, involve costs of misclassification that can be different for both classes. Although providing accurate values for such misclassification costs can be challenging for the user, identifying acceptable misclassification rates is relatively straightforward. In this work, we propose a new TWSVM in which misclassification costs are considered by incorporating performance constraints into the problem formulation. This model is further enriched by performing variable selection (FS), a fundamental task that makes the method more interpretable and efficient. Numerical results demonstrate the effectiveness of the proposed method.

3 - Visualizing outliers in functional data with new versions of the epigraph and the hypograph indices

Belén Pulido Bravo, Alba M. Franco-Pereira, Rosa Elvira Lillo Rodríguez

Outlier detection in functional data presents a critical challenge in contemporary data science research. The inherent complexity of these datasets implies working with an infinite dimensional space. Addressing this challenge demands innovative methodologies that yield robust and interpretable results.

In this study, we introduce novel iterations of the epigraph and hypograph indexes, different from those available in the existent literature. These indices allow to transform the original functional dataset into a multivariate one, enabling the application of available outlier detection methods for multivariate datasets. The inherent visual nature of the epigraph and the hypograph indices facilitates intuitive interpretation of outcomes, enabling users to extract insights into identified outliers.

This methodology is validated through comprehensive experimentation on both simulated and real datasets, demonstrating competitive results compared to existing methodologies available in the literature.

4 - Explaining hidden variable interactions inside a model: a comparison study between different methods.

Pablo Morala, Jenny Alexandra Cifuentes Quintero, Rosa Elvira Lillo Rodríguez, Iñaki Ucar

Being able to explain feature importance when explaining model predictions has been the main focus of Explainable Artificial Intelligence (XAI) methods. However, many of them assign importance values to single variables instead of taking interactions between variables into account, an effect that usually appears in real life problems. In this work we present a comparison study between some extensions of SHAP values (one of the most widely used interpretability methods) to include interactions, and a novel interpretability approach for neural networks named NN2Poly, which in this study is also used in a surrogate manner to explain other kind of models. Extensive simulations are carried out under different settings, both local and global explanations are compared and ways of computing comparable importance order metrics are presented.

Chair: *Gerhard-Wilhelm Weber*

1 - Stochastic reoptimisation model for inventory management

Zahra Namazian, John Betts, Peter Stuckey

Traditional inventory control approaches typically begin by estimating the demand distribution within a predefined family of distributions based on historical observations. The traditional inventory models use these estimated distributions to find the optimal order policy. However, these approaches often rely on insufficient information, for example, only the mean and standard deviation of demand, which may not adequately capture demand changes over time. By contrast with these approaches, we utilize a Light GBM model to predict the daily demand. By rebuilding the LightGBM model at each time period we track changes over time. Consequently, we propose an innovative approach that integrates the LightGBM model within a two-stage stochastic optimisation framework executed on a daily basis. In particular, by employing this integrated predictive model, we achieve a more responsive tracking of changes in demand and make the replenishment decision through continuous reoptimisation of stochastic programming on a daily basis. The effectiveness of our approach is demonstrated in our case study, a retail company dataset. Where the new approach results in reducing inventory management costs without significantly affecting customer service levels, distinguishing it from traditional approaches.

2 - Natural gas demand forecasting in Mexico with machine learning algorithms to support making decision process during energy transition

Sergio Ibarra, Aida Huerta-Barrientos

Mexican energy pool has a big dependence on natural gas, most of which is imported from the United States of America (USA). In this context a reliable, updated and adaptable tool to forecast natural gas demand in the medium term is required to support the Mexican government making decision process. There are now few studies related to natural gas demand forecast in Mexico, but they are either not updated in terms of historical data and variables used as inputs or they do not use the latest known methods such as Neural Networks (NN) losing the opportunity to leverage most recent forecasting techniques. This study explores natural gas demand forecasting in Mexico using machine learning algorithms to support the energy transition. We compare time series models ARMA & ARIMA and Long Short Term Memory NN based on historical demand data from January 2005 to Nov 2023. Mean Absolute Percentage Error (MAPE), Root Mean Square Error (RMSE), and Akaike Criteria (AIC) reveal each method's strengths and weaknesses depending on data characteristics, like the presence of outliers. Our contribution lies in applying advanced machine learning to Mexican gas demand forecasting, expanding on existing research predominantly focused on countries like China, India, Turkey, and the USA. This work provides valuable insights for stakeholders navigating the energy transition in Mexico, helping optimize infrastructure planning, resource allocation, and energy security.

3 - Solving the two dimensional strip packing problem using reinforcement learning framework

Fatih Burak Akcay, Maxence Delorme

In the 2D Strip Packing Problem (SPP), the objective is to pack items into a fixed-width strip, minimizing the height of the packing. A common approach to solving the SPP efficiently is through decomposition algorithms, which split the problem into primary and secondary sub-problems. The primary problem involves solving a relaxed version of the SPP, like the one-dimensional contiguous bin packing problem or parallel processor scheduling problem with contiguity constraints. Using a feasible solution from the primary problem, the secondary problem constructs a valid SPP solution. If none is found, techniques such as adding a cut or banning the current solution are applied. Various formulations, including integer linear programming models or constraint programming models, exist for the primary problem. Empirical evidence suggests that different solution approaches perform better for different instances, with no single dominating formulation. Our research focuses on developing automated hyper-algorithms capable of selecting the most appropriate method or sequence of methods for solving a given instance, following the trend of integrating machine learning techniques into optimization algorithms. We utilize reinforcement learning to determine which mathematical model to employ in the primary problem, along with other features for incorporation into the decomposition scheme. The proposed framework's performance is evaluated using benchmark datasets.

4 - Prediction of exchange rate changes with monetary policy indexation of FOMC meeting minutes

Jia-Hau Guo, Guan-Yu Lai

We derive four monetary policy indices from FOMC (Federal Open Market Committee) minutes to analyze exchange rate changes in several foreign currencies. These monetary policy indices are found to have significant impacts on foreign currency changes in emerging markets while exchange rate changes in some developed or industrial countries could depend on monetary policy indices from meeting records of their own central banks or central banks of their competitors. Additionally, a monetary policy uncertainty indicator based on entropy is introduced to further improve the prediction of exchange rate changes in certain currencies. We find that the uncertainty of meeting minutes could reduce the market belief in monetary policy stance, and then reduce the impact of monetary policy sentiments on exchange rate variations.

Large Scale Optimization in Air Transportation

Stream: Combinatorial Optimization
Invited session

Chair: [Francois Soumis](#)

1 - Integral Simplex for the Set Partitioning Problem

Francois Soumis, Alpha Saliou Barry, Frédéric Quesnel, Issmail El Hallaoui

For the set partitioning problem, the existence of a sequence of integer solutions with non-increasing costs produced by simplex pivots, permitting to reach optimality was proved by Balas, Padberg 1972. Finding the following term in the sequence can be very time-consuming due to degeneracy. When there is no entering variable that leads to a better integer solution, we use a linear programming sub-problem to find a group of variables to enter the basis to obtain an improved solution which is integer most of the time. When this solution is not integer, we solve a small integer programming problem to obtain a better integer solution. We first, present results for large-scale problems (with up to 500 000 variables) for which optimal integer solutions are obtained, most of the time, without any branching. We also, present the integration of this new approach with column generation and parallelism to solve large-scale bus driver and airline pilot problems. Problems with many thousand tasks are solved 5 to 10 faster than with branch and price based on CPLEX

2 - Integral simplex for generalized set partitioning problems

Alpha Saliou Barry, Frédéric Quesnel, Issmail El Hallaoui, Francois Soumis

The set partitioning problem can be generalized. One generalization is to consider that certain tasks must be covered several times. So it's no longer a partition that's sought, but a set of parts that verify the right number of coverages.

Unlike the set partitioning problem, the graph of integer solutions is no longer connected when the possible arcs are simplex pivots. However, in order to restore the connectedness of the graph, it is possible to add artificial variables locally, which allow new pivots to be made while preserving the integrity of the solution.

We give priority to pivots that keep the solution integer. When this is no longer possible, we solve a linear program to obtain a non-degenerate sequence of simplex pivots to perform in order to improve the solution. When this improved solution is still not integer, in some cases the pivot sequence allows to add an artificial column associated with an integer artificial point. The linear program is solved again from this point to find the remaining pivots to be performed in order to obtain a better integer solution. If integrity is still not reached, a branching is performed.

We present results for large pairing problems (around 2,000 constraints and 300,000 variables) and show that the method is around 2 to 5 times faster than traditional methods (CPLEX) and that in many cases, the addition of the artificial variable effectively allows moves on integer points not directly accessible by pivot.

3 - The crew split problem: team creation for the cabin crew pairing problem with several qualification classes and varying requirements.

Frédéric Quesnel, Mohand Ryad Chelbani, Francois Soumis

It is usually beneficial for airlines that cabin crews travel in teams for entire pairings (sequence of flights, connections, and rest, forming one or several days of work). In addition to improving morale and team efficiency, travelling in teams increases the robustness of the schedule. However, different flights may have different crew requirements, so it

is not always possible to have a whole team work on two consecutive flights. In those cases, it may be beneficial to use a core team to cover most of the requirements and use complementary crews to cover the missing assignments. Finding the optimal way to form teams has been identified as an issue but has never been tackled.

In this talk, we formulate the crew split problem, whose role is to determine the core team composition of each flight as well as the complementary crews that will join it. It is a multi-objective optimization problem that, among others, maximizes the size of each core team, minimizes the estimated connexion times, and minimizes the estimated deadhead costs. In addition, our model allows for downranking, which is the possibility of a higher-ranked crew to work a lower-ranked position. We show the benefits of using the crew split problem on a large real-world instance.

1 - Detecting and Handling Reflection Symmetries in MINLP

Christopher Hojny

A symmetry of a mixed-integer nonlinear program (MINLP) is a bijective map that transforms feasible solutions into feasible solutions while preserving the objective value. Already for linear problems it is well known that symmetries can negatively impact the performance of branch-and-bound methods, since symmetric regions of the search space will be repeatedly explored without providing new information. Most of the existing approaches for detecting symmetries focus on permutation symmetries that exchange the order of entries in a solution vector. For many problems classes, however, permutation symmetries do not capture all symmetries. For example, when packing objects into rectangular containers, also reflection symmetries of the container can be taken into account.

In this talk, we present a novel mechanism for computing, next to permutation symmetries, also reflection symmetries of MINLPs. As existing approaches for permutation symmetries, we introduce a suitable graph whose automorphisms correspond to symmetries of a MINLP. Since reflection symmetries may nontrivially interact with nonlinear functions of a MINLP, however, our graph is much more involved than the previously known symmetry detection graphs. We also briefly discuss generalizations of state-of-the-art symmetry handling methods to reflection symmetries. The talk is concluded by numerical experiments showing the effect of handling reflection symmetries in the MINLP solver SCIP.

2 - A generalization of the Weight Reduction algorithm

Aurelio Oliveira, Carla Ghidini, Jonathan Solis Hidalgo

We propose a new linear programming algorithm that arises from the generalization of the weight reduction algorithm, which, in its turn, is based on the von Neumann algorithm. The algorithm developed by von Neumann has important features, such as fast initial convergence and low computational cost to obtain the search direction, which are inherited by both: the weight reduction algorithm and by the present generalization. However, its usefulness is limited due to considerably slow convergence. Thus, with the objective of improving the performance of the weight reduction algorithm, the idea is to consider more than two columns to compute the direction. It is computed considering p coordinates, choosing $p/2$ columns that form the smallest angles with the residue and $p/2$ columns for the largest angles. The advantage of this new algorithm is that by using more columns it is possible to find a better direction. Computational experiments are performed and the

results show that with the new algorithm there is a faster decrease in the residual value as the p value increases. Also, the number of iterations and processing time necessary to determine a good solution for the problem, reduces with the value of p . The generalized algorithm can also be used together with other methods, such as interior point methods. It can be used, for instance, to obtain an advanced starting point and, thus, improving its efficiency.

3 - Certifying Symmetry Handling Reductions in Integer Programming

Jasper van Doornmalen, Leon Eifler, Ambros Gleixner, Christopher Hojny

Modern solvers for mathematical optimization problems are complex pieces of software. They usually make use of a combination of solution methods. Though the correctness of these methods is often proven on paper, with today's tools it seems prohibitively difficult to verify that they are implemented correctly in complex software. Even thoroughly tested state-of-the-art solvers used by many are not immune to bugs and numerical issues. We present a proof system allowing for establishing correctness of results produced by optimization algorithms. Particular focus is placed on mixed-integer programming (MIP), extending on work for binary programs by Bogaerts, Gocht, McCreesh, and Nordström (2022). Our proof system covers a broad range of MIP solving techniques, including cutting planes, presolving, and symmetry handling.

4 - Specialized interior point method for support vector machines based on variable splitting

Jordi Castro

Variable splitting has traditionally been employed in (first order) Lagrangian decomposition approaches and, more recently, in the Alternating Direction Method of Multipliers (ADMM). In this presentation we will show how variable splitting can be efficiently used within (second order) interior point methods for solving large support vector machine (SVM) problems, a binary classification technique extensively used in machine learning. Briefly, by replicating variables, the SVM problem can be decomposed into smaller SVMs with additional linking constraints that equate the values of the different copies. The resulting problem's structure can be exploited by specialized interior point methods that compute the Newton direction with a combination of direct and iterative solvers (i.e., Cholesky factorizations and preconditioned conjugate gradients). This new approach is compared with state-of-the-art solvers for SVMs, which are based on either interior point algorithms (such as SVM-OOPS) or specific algorithms developed by the machine learning community (such as LIBSVM).

1 - Enhancing Business Education through Bayesian Knowledge Tracing: A Framework for Personalized Learning

Nicolas Nunez

Our research addresses the limited use of Learning Analytics tools and techniques in providing personalized learning experiences for MBA students. We propose a novel framework that incorporates Bayesian Knowledge Tracing (BKT) and other predictive modeling techniques to create customized learning tracks for MBA programs. Our approach leverages data from standardized admission tests and student performance to generate tailored recommendations, addressing a significant gap in the application of learning analytics in graduate business education.

Preliminary results, based on a small sample, indicate that the use of BKT can improve the learning experience for MBA students. By developing a clear framework for implementing BKT and other predictive modeling techniques, this research aims to provide academic directors, deans, and key decision-makers in graduate business schools with a practical tool for enhancing personalized learning in their programs.

The proposed framework has the potential to be adapted for a broader audience beyond MBA programs, contributing to the advancement of personalized learning in various educational contexts. This research aligns with the growing need for data-driven approaches to optimize learning outcomes and student success in higher education.

2 - Guiding labeling efforts in question difficulty estimation using active learning

Arthur Thuy, Dries Benoit

Estimating the difficulty of exam questions is crucial for effectively evaluating students' knowledge and facilitating personalized exercise recommendations. Obtaining labels for the training dataset typically involves time-consuming and expensive pretesting and manual calibration. Despite recent advances in fine-tuned Transformer-based models outperforming traditional machine learning approaches, the labeling expenses remain considerable. Our study addresses this labeling challenge by leveraging active learning to drive the annotation process, directing human expert attention toward the most informative data points. Given the lack of uncertainty in standard regression neural networks, we employ Monte Carlo Dropout to capture model uncertainty in predictions on the unlabeled set. Model uncertainty tends to be high on data points in underrepresented areas of the input space, precisely the observations we aim to label. Fine-tuning a DistilBERT model with Monte Carlo Dropout on a dataset comprising science and math multiple-choice questions yields promising results.

3 - Cross-Lingual Debiasing of Large Language Models

Manon Reusens, Philipp Borchert, Margot Mieskes, Jochen De Weerd, Bart Baesens

Bias detection and mitigation have received more and more attention over the last few years in Natural Language Processing (NLP). This is mainly due to the societal implications. While often research into these debiasing techniques focuses on English and mostly monolingual models, our research aims to provide insights into the cross-lingual transferability of these debiasing techniques. More specifically, we look into what happens to the other languages when debiasing a multilingual model in one language. We examine several languages such as English, French, German, and Dutch. The CrowS-Pairs dataset includes stereotypes associated with historically disadvantaged groups in the United States encompassing multiple types of bias, among which gender, race, and religion. From this dataset also a French version exists, addressing stereotypes against specific demographic groups in France. For the other languages, we used translations of the dataset that were checked by native speakers. Next, we analyzed the effects of cross-lingual debiasing on multilingual BERT (mBERT). Using these translations of the CrowS-Pairs dataset, we find that cross-lingual debiasing is possible. Moreover, we identify SentenceDebias as the best-performing debiasing technique from our set. Finally, we find that the debiasing techniques that add an additional pretraining step are best employed on the lowest resource languages.

4 - Predictive Politics: Understanding Drivers of Engagement in Belgian Politics

Dylan Van Mulders, Matthias Bogaert, Dirk Van den Poel

Social media platforms have offered politicians and political parties new opportunities to communicate and interact with citizens. Especially in Belgium, political parties and politicians are spending a lot of money to social network sites to attract voters. Backed by Belgian party financing, Belgian parties have been among the biggest spenders in Europe, even outside of campaign periods. The main goal of this research is to gain a deeper understanding on the online engagement with political posts within the Belgian multi-party system. We focus on what politicians are talking about and how people engage with this on X, formerly known as Twitter, since it remains one of the most political social network sites to date. To achieve this, we propose a two-step approach to predict the level of engagement based on a unique set of features. This approach first classifies tweets into several like-minded categories, and then applies regression on each category. Supported by the Academic Twitter API we analyzed the posts of 72 Belgian politicians as well as posts from all the major political party Twitter profiles for a period of 2 years. The main contribution of this study is that it is the first to combine the added value of multiple distinct characteristics in the context of online engagement and disclose differences between posts originating from personal and party profiles within a multi-party political system.

1 - Adaptive Quasi-Newton and Anderson Acceleration Framework with Explicit Global (Accelerated) Convergence Rates

Damien Scieur

Despite the impressive numerical performance of the quasi-Newton and Anderson/nonlinear acceleration methods, their global convergence rates have remained elusive for over 50 years. This study addresses this long-standing issue by introducing a framework that derives novel, adaptive quasi-Newton and nonlinear/Anderson acceleration schemes. Under mild assumptions, the proposed iterative methods exhibit explicit, non-asymptotic convergence rates that blend those of the gradient descent and Cubic Regularized Newton's methods. The proposed approach also includes an accelerated version for convex functions. Notably, these rates are achieved adaptively without prior knowledge of the function's parameters. The framework presented in this study is generic, and its special cases include algorithms such as Newton's method with random subspaces, finite differences, or lazy Hessian. Numerical experiments demonstrated the efficiency of the proposed framework, even compared to the l-BFGS algorithm with Wolfe line-search.

2 - Accelerated Adaptive Cubic Regularized Quasi-Newton Methods

Dmitry Kamzolov

In this paper, we propose the first Quasi-Newton method with a global convergence rate of $\mathcal{O}(\frac{1}{R^2k})$ for general convex functions. Quasi-Newton methods, such as BFGS, SR-1, are well-known for their impressive practical performance. However, they are theoretically slower than gradient descent for general convex functions. This gap between impressive practical performance and poor theoretical guarantees was an open question for a long period of time. In this paper,

we make a significant step to close this gap. We improve upon the existing rate and propose the Cubic Regularized Quasi-Newton Method with a convergence rate of $\mathcal{O}(\frac{1}{R^2k})$. The key to achieving this improvement is to use the Cubic Regularized Newton Method over the Damped Newton Method as an outer method, where the Quasi-Newton update is an inexact Hessian approximation. Using this approach, we propose the first Accelerated Quasi-Newton method with a global convergence rate of $\mathcal{O}(\frac{1}{R^2k^2})$ for general convex functions. In special cases where we have access to additional computations, for example Hessian-vector products, we can improve the inexact Hessian approximation and achieve a global convergence rate of $\mathcal{O}(\frac{1}{R^3k^3})$, which make it intermediate second-order method. To make these methods practical, we introduce the Adaptive Inexact Cubic Regularized Newton Method and its accelerated version, which provide real-time control of the approximation error. We show that the

3 - On the behavior of limited-memory quasi-Newton methods for quadratic problems

Aban Ansari-Önnestam, Anders Forsgren

Quasi-Newton methods form an important class of methods for solving nonlinear optimization problems. In such methods, first order information is used to approximate the second derivative. The aim is to mimic the fast convergence that can be guaranteed by Newton-based methods. In the best case, quasi-Newton methods will far outperform steepest descent and other first order methods, without the computational cost of calculating the exact second derivative. These convergence guarantees hold locally, which follows closely from the fact that if the objective function is strongly convex it can be approximated well by a quadratic function close to the solution. Understanding the performance of quasi-Newton methods on quadratic problems with a symmetric positive definite Hessian is therefore of vital importance. In the classic case, an approximation of the Hessian is updated at every iteration and exact line search is used. It is well known that the algorithm terminates finitely, even when the Hessian approximation is memoryless, i.e. requires only the most recent information. This talk will address ways in which the reliance on exact line search and dependence on conjugate search directions can be relaxed, and how these changes affect the behavior of quasi-Newton methods.

4 - Advancing the lower bounds: An accelerated, stochastic, second-order method with optimal adaptation to inexactness

Artem Agafonov, Dmitry Kamzolov, Alexander Gasnikov, Ali Kavis, Kimon Antonakopoulos, Volkan Cevher, Martin Takac

We present a new accelerated stochastic second-order method that is robust to both gradient and Hessian inexactness, which occurs typically in machine learning. We establish theoretical lower bounds and prove that our algorithm achieves optimal convergence in both gradient and Hessian inexactness in this key setting. We further introduce a tensor generalization for stochastic higher-order derivatives. When the oracles are non-stochastic, the proposed tensor algorithm matches the global convergence of Nesterov Accelerated Tensor method. Both algorithms allow for approximate solutions of their auxiliary subproblems with verifiable conditions on the accuracy of the solution.

Stochastic Optimization: Advanced Applications

Stream: Stochastic, Robust and Distributionally Robust Optimization

Invited session

Chair: Giovanni Pantuso

1 - Trust Dynamics and Collaboration Costs: Navigating Complexity in Collaborative Distribution Networks

Reza Alikhani, Mahnaz Hosseinzadeh

In collaborative distribution networks, building partnerships hinges on intricate trust dynamics. The exchange of critical information is crucial, but when a host carrier holds sensitive data, like customer demands, challenges arise. The host's comprehensive data is pivotal, yet asymmetry may deter reciprocation, impacting collaboration. To surmount this, we use bi-objective two-stage robust optimization, employing an extended algorithm for effective resolution. Our framework navigates collaboration costs, offering insights into the intricate interplay with network design. Our study delves into trust's profound impact, enhancing understanding of collaboration dynamics in distribution networks.

2 - Optimal Participation of Energy Communities in Electricity Markets under Uncertainty. A Multi-Stage Stochastic Programming Approach.

Albert Solà Vilalta, Marlyn Dayana Cuadrado Guevara, Ignasi Mañé, F.-Javier Heredia

An energy community is a legal figure, recently coined by the European Union, that creates a framework to encourage active participation of citizens and local entities in the energy transition to net-zero. In this work, we study the optimal participation of energy communities in day-ahead, reserve, and intraday electricity markets.

The motivation to do so is that there are time periods where energy communities cannot meet their internal demand, and periods where they generate excess electricity. This is because most of the electricity they generate comes from variable renewable resources like solar and wind. Electricity market participation is a natural way to ensure they meet their internal demand at all times, and, simultaneously, make the most of the excess electricity.

We propose a multi-stage stochastic programming model that captures variable renewable and electricity price uncertainty. The multi-stage aspect models the different times at which variable renewable generation is considered to be known and electricity prices from different markets are revealed. This results in a very large scenario tree with 34 stages, and hence a very large optimization problem. Scenario reduction techniques are applied to make the problem tractable. Case studies with real data are discussed, considering different energy community configurations, to analyse proposed regulatory frameworks in Europe. The added value of considering stochasticity in this problem is also analysed.

3 - A bivariate two-moments fit and its application in appointment scheduling

Bharti Bharti, Michel Mandjes, René Bekker

The optimization of appointment scheduling within parallel server systems is important for enhancing operational efficiency and customer satisfaction in diverse service industries, ranging from healthcare and telecommunications to transportation and manufacturing. In this context, we tackle the challenge of appointment scheduling in systems where clients are served by two correlated servers operating in parallel, with given distribution. We devise a stochastic optimization framework to minimize a comprehensive loss function that balances clients' waiting times, server idle times, and the effects of individual client's sojourn times. To capture the diverse operational scenarios encountered in practice, we introduce novel metrics, including maximum and minimum sojourn times, reflecting real-world constraints and priorities and redefine the scheduling objective solely in terms of sojourn times, facilitating the application of standard optimization methodologies. To accurately model the distributions of sojourn times, we propose a bivariate extension of the conventional two-moments fit using Weibull distribution and leverage the Frechet bounds for bivariate distributions with fixed marginals to get bounds on correlation between the two queues. Finally we conduct a series of numerical experiments to illustrate the efficiency of our method. We compare our method with simulated results and examine the effect for both negative and positive correlations with different distributions.

4 - Optimal carsharing service pricing under decision-dependent demand uncertainty

Jiali Deng, Giovanni Pantuso

In carsharing pricing problems, stochastic demand is typically viewed as an exogenous random variable, where the uncertainty is governed by known probability distributions. This assumption neglects the inherent correlation between up-to-date user's adoption decisions and the released carsharing prices, which makes the stochastic demand decision-dependent. To this end, we come up with an optimal carsharing service pricing problem that incorporates endogenous uncertainty of carsharing demand, specifically by accounting for the decision-dependent distributions of stochastic demand. The problem is formulated as a two-stage mixed-integer stochastic program with decision-dependent uncertainty. We show that the problem can be written as an equivalent mixed-integer bilinear program whose size is exponential in the input parameters. To tackle the computational complexity we adopt a version of the L-shaped method which accounts for decision-dependent distributions. The computational experiments demonstrate empirically that the algorithm converges finitely. In addition, the method outperforms by far a commercial solver used to solve the monolithic formulation, hereby extending the domain of practically tractable problems.

1 - Stability in games with random payoffs

Lukáš Račko, Milos Kopa, Petr Lachout

The paper deals with non-cooperative games in which the payoff function of its players is influenced by exogenous randomness. The main goal is to provide a general concept of stability in those games because the standard notion of Nash equilibrium is no longer satisfactory. One could find a deterministic equivalent to the game with a random payoff by considering a risk measure and defining a new game with a payoff function adjusted by the risk measure. This, however, causes several problems as the Fundamental Theorem of non-cooperative game theory no longer holds for most of such defined equivalents. Our idea is to loosen the standard concept of the best response to an alpha-best response which requires the strategy to be the best response only with a certain high probability. Based on this idea we define the alpha-Nash equilibria and we prove that for every finite game with random payoff non-trivial alpha-Nash equilibria exist. Moreover, those equilibria characterize equilibria in a broad class of deterministic equivalent games. Finally, we extend the idea of a static game with a random payoff to a game with multiple stages and we show that every finite stochastic game may be represented as a sequential game with a random payoff. In the numerical study, this theory is applied to a management problem of competition of hospitals for vaccines during a pandemic.

2 - Epidemic model of a misinformation spread?

Martin Smid

We introduce a mathematical framework for modeling the dissemination of an undesirable agent, encompassing both biological pathogens and misinformation. This framework is articulated as a heterogeneous, partially observable vector auto-regression (VAR) model. In epidemiological terminology, it can be described as a stochastic SEIR-like model.

The utility of a closely related model has been previously validated through its application in analyzing and formulating policy recommendations during the COVID-19 pandemic. In this study, we elaborate on the modifications necessary for adapting this model to accurately represent the dynamics of undesirable content propagation, with empirical validation provided through analysis of data derived from social networks.

3 - Dual solutions in convex stochastic optimization

Ari-Pekka Perkkiö

We study duality and optimality conditions for general convex stochastic optimization problems. The main result gives sufficient conditions for the absence of a duality gap and the existence of dual solutions in a locally convex space of random variables. It implies, in particular, the necessity of scenario-wise optimality conditions that are behind many fundamental results in operations research, stochastic optimal control and financial mathematics. Our analysis builds on the theory of Frechet spaces of random variables whose topological dual can be identified with the direct sum of another space of random variables and a space of singular functionals. The results are illustrated by deriving sufficient and necessary optimality conditions for several more specific problem classes. We obtain significant extensions to earlier models e.g. on stochastic optimal control, portfolio optimization and mathematical programming.

4 - Risk-Averse Multiarmed Bandits with Switching Penalties

Milad Malekipirbazari

This work explores the intricate dynamics of the multiarmed bandit (MAB) problem, augmented with a critical realworld consideration: the cost implications of switching decisions. This study is at the forefront of integrating risk considerations into MAB scenarios, where decision-makers face penalties each time they transition between options. Such scenarios are not just theoretical constructs but are reflective of numerous practical applications. Our work distinguishes itself by addressing the largely unexplored domain of risk-averse MAB problems compounded by switching penalties. Our contribution is threefold: firstly, we explore the qualitative aspects of optimal policies. Secondly, we present novel theoretical results, including the development of the Risk-Averse Switching Index (RASI), which addresses the dual challenges of risk aversion and switching costs, demonstrating its near-optimal efficacy. Lastly, through rigorous numerical experiments, we validate our algorithm's effectiveness and practical applicability.

1 - Priority queues with competitive servers

Binyamin Oz, Elisheva Zur

We consider a queueing system with competitive revenue maximizing servers who charge for priority. Customers are strategic and decide which server to seek service from and whether to pay for priority. Through an analysis of the equilibrium in this sequential two-stage game, we demonstrate that the system exhibits self-regulation. Specifically, contrary to systems lacking priority mechanisms, our findings reveal that socially optimal joining rates are attained.

2 - Incentive-Compatible Cost Allocations for Inventory Games with Private Information

Yinlian Zeng

In this paper we design cost allocation rules for inventory games with private information. First, we design incentive-compatible cost allocation rules for inventory games with private information via Vickrey-Clarke-Groves (VCG) rules. Then, we propose incentive-compatible and approximate budget-balanced cost allocations via polynomial approximations such as the Chebyshev approximation and the Taylor approximation. In addition, we propose an incentive-compatible cost allocation with individual rationality. Finally, we conduct numerical experiments to compare the performance of the proposed cost allocations.

3 - A Variable Horizon Stability Concept for Partially Known Preferences in Bilateral Conflicts

Leandro Rêgo, Emerson R Sabino

Conflict analysis is a research area that using mathematical models represents and studies the evolution of conflicts in a systematic way. The Graph Model for Conflict Resolution (GMCR) is a successful model in this area due to its flexibility and relative ease of use. In GMCR, many stability concepts try to capture different behavioral characteristics of decision makers (DMs) in conflicts. In this paper, a stability concept is proposed for the GMCR that is useful in applications where DMs do not have full knowledge about their opponents' preferences. As in real conflicts there are factors that may make it difficult to fully obtain information about others' preferences, to understand DMs' behavior in such a scenario is valuable. With our proposed stability concept, it is possible to carry out a stability analysis in the GMCR even if only part of the preference information is known. The Variable Horizon with Partially Known Preferences Stability works by anticipating what a given DM believes that final conflict state would be after any chosen number of moves and countermoves following its initial move in a bilateral conflict. The proposed solution concept generalizes two important stability notions, limited-move stability and maximin stability, which are particular cases when DMs have full knowledge and no knowledge at all, respectively. Finally, an application of a dispute among two Brazilian states about a certain geographical area is made with the proposed stability.

1 - A Combined Framework of MCDA and MOP Methods for Planning High School Student Distribution in the Capital Region of Denmark.

Andreas Sølling Brendstrup, Valdemar Buch, Michael Bruhn Barfod, Thomas Stidsen

Many real-life problems frequently encompass multiple, sometimes conflicting, objectives that require simultaneous consideration. For this purpose, there is a need for a comprehensive assessment methodology. Multi-criteria decision analysis (MCDA) and multi-objective optimization problems (MOP) are methodologies attempting to overcome such problems. MCDA focuses on deriving a satisfactory solution while accounting for a stakeholder preference structure. MOP methodologies focus on the optimization tasks of identifying Pareto optimal solutions, where optimal solutions must be taken in the presence of a trade-off between two or more conflicting objectives. Over the past decade, extensive research has been conducted, resulting in substantial bodies of literature on both subjects, revealing potential opportunities and synergies between them. This presentation investigates the possible combination of MOP and MCDA methods in a novel framework to address large, complex decision problems involving conflicting objectives and several stakeholders. The framework will be tested on the combinatorial problem of distributing high school students within the capital region of Denmark.

2 - StudyPlanner: Helping students to plan university courses with integer programming

Andreas Wiese, Michael Ritter, Philipp Wiedmann

At the beginning of each semester, all university students need to plan the courses they want to take this semester. In the process, they need to take into account the rules of their degree program. Those might, for example, regulate that some courses are compulsory, that one needs to complete a certain number of credits from a group of courses, or that one needs to choose a study focus from some given options. Also, there are additional considerations, such as the preferences of the student for certain subjects, the times when the courses are scheduled, or that some courses need to be taken in a certain order. In particular, it is a good idea to not just plan the courses of the upcoming semester, but all courses in all future semesters.

This leads to an optimization problem with multiple objectives that include, for example, minimizing the time until graduation and maximizing the satisfaction of the student with the selected courses. We propose an integer programming (IP) formulation for this problem and apply it to the Bachelor and Master degree in Mathematics at the Technical University of Munich (TUM). In our computational experiments, we could solve most of the tested instances in about one second using the non-commercial IP solver SCIP, and even faster with Gurobi. We made our planning tool available to the students of the Department of Mathematics at TUM. It is publicly accessible at <https://studyplanner.co.cit.tum.de>.

3 - A Lagrangian Bounding and Heuristic Principle for Bi-Objective Discrete Optimization

Nils-Hassan Quttineh, Torbjörn Larsson, Ida Åkerholm

Lagrangian relaxation is a common and often successful way to approach computationally challenging single-objective discrete optimization problems with complicating side constraints. Its aim is often two-fold; first, it provides bounds for the optimal value, and, second, it can be used to heuristically find near-optimal feasible solutions, the quality of which can be assessed by the bounds. We consider bi-objective discrete optimization problems with complicating side constraints and extend this Lagrangian bounding and heuristic principle to such problems. The Lagrangian heuristic here produces non-dominated candidates for points on the Pareto frontier, while the bounding forms a polyhedral outer approximation of the Pareto frontier, which can be used to assess the quality of the candidate points. As an illustration example we consider a facility location problem in which both CO₂ emission and cost should be minimized. The computational results are very encouraging, both with respect to bounding and the heuristically found non-dominated solutions. In particular, the Lagrangian bounding is much stronger than the outer approximation given by the Pareto frontier of the problem's linear programming relaxation.

4 - A General Label Setting Algorithm for the Multiobjective Temporal Shortest Path Problem

Clemens Thielen, Cristina Bazgan, Johannes R. Kager, Daniel Vanderpooten

Graphs in which the arc set changes over time (in discrete steps), are called temporal graphs. Given a directed temporal graph, a start node s , and a constant number of objectives, the task in the single-source multiobjective temporal shortest path problem consists of computing the set of nondominated images of temporal paths from s to every other node as well as one corresponding efficient path for each of these images. This problem generalizes both the multiobjective shortest path problem in static graphs and the singleobjective temporal shortest path problem.

This talk presents a general label setting algorithm for the single-source multiobjective temporal shortest path problem that can handle a large variety of different objectives. The only condition imposed on the objectives is a monotonicity property that generalizes the nonnegativity of the arc costs required for the well-known label setting algorithm for solving the static single-source shortest path problem in both the singleobjective and the multiobjective case. The worst-case running time

of our algorithm is polynomial in the sum of the input size of the problem instance and the number of nondominated images, which means that it runs in polynomial time for all tractable versions of the problem.

To complement this result, we provide a complete classification into tractable and intractable problems for all single-source multiobjective temporal shortest path problems involving a large variety of objectives.

1 - Lagrangian duality for Mixed-Integer Semidefinite Programming

Renata Sotirov, Frank de Meijer

Mixed-integer semidefinite programming can be viewed as a generalization of mixed-integer programming where the vector of variables is replaced by mixed-integer positive semidefinite matrix variables. The combination of positive semidefiniteness and integrality allows to formulate various nonlinear optimization problems as mixed-integer semidefinite programs (MISDPs). In this talk we show that MISDPs induce bounds based on Lagrangian duality theory. By introducing MISDP-based projected bundle algorithm, we show that the resulting Lagrangian dual bounds are stronger than the standard SDP bounds for various optimization problems.

2 - Linear Convergence of Fixed-Point Iteration of Averaged Operators via a Generic Error-Bound Condition

Kira van Treek, Javier Peña, Juan Vera, Luis Zuluaga

Several optimization algorithms, including the ADMM and Douglas-Rachford algorithm (DR), can be cast as the fixed-point iteration (FPI) of an averaged operator. However, the convergence of these algorithms is slow in general (within sublinear regime). We show linear convergence of the FPI of averaged operators by leveraging an error-bound condition on the operator. Our work captures several existing results on the linear convergence of the ADMM and DR under stronger assumptions. As a byproduct of our method, we bound the rate of convergence of the DR applied to linear and quadratic optimization problems.

3 - Relaxations for the elementary shortest path problem

Mirjam Duer, Regina Schmidt

Given a directed graph with negative edge costs and possibly negative cycles, the elementary shortest path problem consists in finding a shortest elementary path, i.e., a path from a source node to a target node that visits each node at most once. In this talk, we discuss various formulations and relaxations for this NP-hard problem.

Reliability Models

Stream: Stochastic Modelling

Invited session

Chair: Bram de Jonge

1 - Modelling lifetimes of systems operating under load conditions

Juana-Maria Vivo-Molina, Manuel Franco

Systems with components operating under load conditions are vulnerable to failure, becoming more difficult the maintenance decision-making. Such fragility increases under structural dependency, which is commonly used for configuring systems as a cost-effective technique that optimize the reliability and availability. In this study, we develop a stochastic distribution to model lifetimes of systems with structural dependence under preventive maintenance policies. Further, a real-world case study is provided to illustrate the effectiveness of the proposed family.

2 - Condition-based Maintenance for a Degrading System under Dynamic Working Conditions

Guo Shi, Bin Liu, Lesley Walls

This study proposes a maintenance strategy for a degrading system under dynamic working conditions. Dynamic working conditions including environmental factors such as temperature, and humidity, alongside operating factors like production rate and operating speed, present challenges in accurately capturing the degradation process. In addition, the heterogeneity among observed components adds complexity to utilising the health monitoring data. To address these issues, we utilise Bayesian Linear regression and Bayesian Poisson regression to account for shock occurrence and magnitude. During system operation, regression parameters are updated upon the arrival of shocks at each decision epoch. We formulate the optimal maintenance problem as a Markov decision process, with decisions triggered by parameter updates converging towards underlying values. This paper not only establishes an analytically tractable degradation model incorporating component heterogeneity and dynamic working conditions but also theoretically explores the structure of optimal preventive maintenance thresholds. Additionally, to ease the computational burden due to the high state space, we introduce a heuristic algorithm that leverages the most likely distribution. Numerical experiments and a case study validate the effectiveness of the proposed maintenance policy, demonstrating its practical applicability and efficacy in real-world scenarios.

3 - Data-Driven Condition-Based Maintenance Optimization Given Limited Data

Yue Cai, Bram de Jonge, Ruud Teunter

Unexpected failures of operating systems can result in severe consequences and huge economic losses. To prevent them, preventive maintenance based on condition data can be performed. Existing studies either rely on the assumption of a known deterioration process or an abundance of data. However, in practice, it is unlikely that the deterioration process is known, and data is often limited (to a few runs-to-failure), especially for new systems. This paper presents a fully data-driven approach for condition-based maintenance (CBM) optimization that is especially useful in situations with limited data. The approach uses penalized logistic regression to estimate the failure probability as a function of the deterioration level and allows any deterioration level to be selected as the preventive maintenance threshold, also those that have not been observed in the past. Numerical results indicate that the preventive maintenance thresholds resulting from our proposed approach closely approach the optimal values.

4 - Data-Driven Condition-Based Maintenance Optimization

Bram de Jonge

Most studies on condition-based maintenance optimization consider the deterioration process of an industrial system to be known. In contrast, we make the more realistic assumption of an unknown deterioration process and develop approaches for determining when to carry out maintenance based on limited obtained condition data. We also assume that the parametric form of the deterioration process is unknown; our approaches are therefore fully data-driven. We analyze how the quality of the decisions depends on the amount of data that is available.

1 - Cooperative solution to noncooperative game

Zvi Winer, Avishay Aiche

Content analysis reveals that in many markets in the State of Israel where regular payment is required for continuous service, usually monthly, a situation can be seen where the price of the service creeps up consistently and even though the consumer has an option to switch to another company, at the starting price he paid, he remains loyal to the company that increases its service consistently and continuously. The purpose of this paper is to provide a theoretical model according to which the company that raises its' price capitalize on the consumer loyalty. The subgame perfect equilibrium resulting from the model supports the empirical evident. According to the perfect equilibrium the firm initially offers loss prices, the consumer remains loyal to the firm and the prices in subsequent periods compensate for the loss in the first periods.

2 - Personalized dynamic pricing: pearls or perils?

Baile Lu, Hongyan Dai, Weihua Zhou

Leveraging large-scale data sources to employ personalized dynamic pricing has been a prominent practice in the retail industry. However, the outcome of this pricing strategy could be mixed. Therefore, this study aims to empirically investigate the impact of personalized dynamic pricing on store performance and individual consumer behavior under different conditions. We obtain unique access to a large data set from a leading on-demand delivery platform that has launched a personalized dynamic pricing strategy through price discounts in some of its grocery stores. Employing a quasi-experimental setting, we utilize the difference-in-differences method to estimate the causal impact of personalized dynamic pricing. First, we conduct store-level analyses and find that personalized dynamic pricing decreases store revenue. Then, to understand the underlying mechanism, we proceed with individual-level analyses and find that personalized dynamic pricing increases the individual transaction amount and frequency while increasing consumer churn. Finally, we investigate the moderating effects of an essential feature of personalized dynamic pricing: the price fluctuation over time. We find that a bit more fluctuation can mitigate the negative consequences of personalized dynamic pricing by reducing consumer churn and increasing consumer transaction activities. However, too much price fluctuation intensifies the negative consequences of personalized dynamic pricing.

3 - A game theoretical analysis on penalty of online copyright infringement with an empirical study

I-Hsuan Hong, Jack C.P. Su, Ching-Kuan Tsai

The increasing societal emphasis on intellectual property rights and the rampant proliferation of pirated products have led to the gradual significance of corresponding legal frameworks and penalties. This study aims to explore the optimal determination of punitive damages for intellectual property infringement on pirated video platforms under various circumstances, with an empirical study serving as validation. Initially, a utility function is established to determine consumer behavior. The primary objective of this study is to investigate the Stackelberg game model with publishers as leaders and legal platform operators, as well as pirated platform operators, as followers. Subsequently, an analysis of infringement behavior across different scenarios is conducted, assessing how the magnitude of punitive damages impacts publisher revenue. An empirical study is then conducted to validate the relationship between the theoretical model and case study. The overall goal of this research is to provide more concrete and effective methods and

strategies for addressing intellectual property infringement issues on online video platforms.

4 - Forecasting behaviour in instable environments

Ulrike Leopold-Wildburger

Time series models face structural instability when applied to real data. Usually, studies yield to applications without the consideration of breaks leads to unreliable results. Progress has been achieved in the theory of identifying, estimation and testing of structural instabilities. Our experimental study shows who efficient the so-called bounds & likelihood heuristic can be. The subjects quickly identify breaks and are able to adapt their forecasts.

Time series models face structural instability when applied to real data. Usually, studies yield to applications without the consideration of breaks leads to unreliable results. Progress has been achieved in the theory of identifying, estimation and testing of structural instabilities by our new procedure. The experimental studies show how efficient the so-called bounds & likelihood heuristic can be. The subjects quickly identify breaks and are able to adapt their forecasts in a surprisingly good manner. The subjects can be well explained by the b&l model despite the occurrence of structural breaks. The bounds & likelihood heuristic manages to model average (not individual) forecasts.

Structured nonconvex optimization

Stream: Nonsmooth Optimization

Invited session

Chair: [Susan Ghaderi](#)

1 - Regularization Methods for Sparse Optimization with Applications

Carisa K.W. Yu, Siu Kai Choy

Sparse optimization is a practical approach for tackling numerous big data challenges. Extensive empirical studies in the field have demonstrated that nonconvex regularization methods exhibit a significantly stronger sparsity capability to promote sparsity and a notably more robust stability in sparse recovery compared to convex penalty methods. In this paper, we explore various nonconvex regularization models to address sparse optimization problems. Theoretical analysis is conducted to establish recovery bounds for these regularization models. Additionally, we propose the widely recognized proximal gradient method so as to solve the regularization problems and establish convergence rates for the numerical algorithms. Finally, we apply our theoretical findings and numerical algorithms to tackle the problem of inferring the master gene regulator in cell fate conversion, presenting compelling numerical results.

2 - High-order proximal point method in the nonconvex setting

Alireza Kabgani, Masoud Ahoosh

The primary objective of this talk is to study exact and inexact versions of the high-order proximal-point methods in the nonconvex setting. The subsequential convergence is investigated by showing the monotonicity of the sequence Lyapunov function values, where our Lyapunov function is the high-order Moreau envelope. We establish the global convergence of the method under Kurdyka-Lojasiewicz inequality. As a specific case study, we will discuss the effectiveness of these algorithms in addressing weakly convex optimization problems through theoretical analyses and numerical results.

3 - First- and second-order models for nonsmooth functions based on derivative sampling

Bennet Gebken

In optimization, many solvers are based on iteratively building a local model of the objective function and then minimizing the model instead of the original function. In the smooth case, such models can be derived from the Taylor expansion based on derivatives of different orders. In the nonsmooth case on the other hand, models are more challenging to construct: The first issue is the lack of a Taylor expansion. While replacing the gradient in smooth first-order methods by the Clarke subdifferential from nonsmooth analysis yields a way to characterize descent directions, there is no simple way to derive higher-order models. The second issue is that generalized derivatives like the Clarke subdiff. are difficult to work with in practice, since they can be unstable and impossible to evaluate in the general case. In this talk, I will present two models for (unstructured) locally Lipschitz continuous functions. The first model is a simple first-order model, which is based on approximating the Clarke subdiff. by the Goldstein eps-subdiff. which, in turn, can be approximated in practice by a deterministic gradient sampling approach. The second model is based on the idea of sampling Hessian matrices in addition to the gradient. More precisely, it is defined as the maximum of (existing) second-order Taylor expansions in a neighborhood of a point. After introducing each model, I will present ways to generate them in practice and discuss the behavior of the resulting descent methods.

4 - Radial Epiderivative based Method in nonconvex Lipschitz Optimization

Gulcin Dinc Yalcin, Refail Kasimbeyli, Erdener Özçetin, Gazi Bilal Yildiz

This study aims to develop a method based on the radial epiderivative, a notion defined for non-convex functions. The method begins with an initial solution. Then, at each iteration, a direction is chosen and evaluated by using the value of the radial epiderivative at the current point. If the direction is decent, a new point is generated in that direction. If not, a new direction is determined, and the process is repeated. Determining directions is a crucial aspect to consider. The study utilizes particle swarm optimization (PSO) and cyclic coordinate (CC) to determine directions at each iteration. Two algorithms, radial epiderivative-based PSO (RPSO) and radial epiderivative-based CC (RCC), are then analyzed. The algorithms' performance is demonstrated on test problems from the literature, and the results are promising.

Iterative Methods for Feasibility and Optimization Problems

Stream: Variational Analysis and Continuous Optimization

Invited session

Chair: [Francisco Javier Aragón Artacho](#)

1 - Local linear convergence of parallel projection algorithms with reduced lifting

Rubén Campoy

Different notions on regularity of sets and of collection of sets play an important role in the analysis of the convergence of projection algorithms in nonconvex scenarios. While some projection algorithms can be applied to feasibility problems defined by finitely many sets, some other require the use of a product space reformulation to construct equivalent problems with two sets. In this work we analyze how some regularity properties are preserved under a reformulation in a product space of reduced dimension. This allows us to establish local linear convergence of parallel projection methods which are constructed through this reformulation.

2 - The Boosted Difference of Convex Functions Algorithm for Value-at-Risk Constrained Portfolio Optimization

Marah-Lisanne Thormann, Vuong Phan, Alain Zemkoho

A highly relevant problem of modern finance is the design of Value-at-Risk (VaR) optimal portfolios. Due to contemporary financial regulations, banks and other financial institutions are tied to use the risk measure to control their credit, market, and operational risks. For a portfolio with a discrete return distribution and finitely many scenarios, a Difference of Convex (DC) functions representation of the VaR can be derived. Wozabal (2012) showed that this yields a solution to a VaR constrained Markowitz style portfolio selection problem using the Difference of Convex Functions Algorithm (DCA). A recent algorithmic extension is the so-called Boosted Difference of Convex Functions Algorithm (BDCA) which accelerates the convergence due to an additional line search step. It has been shown that the BDCA converges linearly for solving non-smooth quadratic problems with linear inequality constraints. In this paper, we prove that the linear rate of convergence is also guaranteed for a piecewise linear objective function with linear equality and inequality constraints using the Kurdyka-Łojasiewicz property. An extended case study under consideration of best practices for comparing optimization algorithms demonstrates the superiority of the BDCA over the DCA for real-world financial market data. We are able to show that the results of the BDCA are significantly closer to the efficient frontier compared to the DCA.

3 - Semi-Newton algorithms in nonsmooth difference programming

Francisco Javier Aragón Artacho

In this talk we present a new coderivative-based Newton algorithm for tackling unconstrained optimization problems whose objective function can be expressed as the difference of two generally nonconvex functions, namely, a continuously differentiable function with locally Lipschitzian derivatives and a locally Lipschitz and prox-regular function. Focusing our attention in the requirement of extended positive-definite properties of the generalized Hessian of the first function, we prove the well-posedness and various convergence results of the proposed algorithm. We conclude with some numerical experiments demonstrating the performance of the proposed algorithm in nonconvex settings.

This is a joint work with Boris S. Mordukhovich and Pedro Pérez-Aros.

Recent advances on Variational Inequalities and Equilibrium Problems I

Stream: Variational Inequalities and Equilibrium Problems: From Theoretical Advances to Real World Applications

Invited session

Chair: *Mauro Passacantando*

1 - A random elastic traffic equilibrium problem: stochastic quasi-variational approach

Annamaria Barbagallo

The aim of the talk is to introduce a random elastic traffic equilibrium problem in a Hilbert space setting (see [1]). The equilibrium condition is expressed by a random extension of the elastic Wardrop principle. Its characterization with a stochastic quasi-variational inequality is proved. Under suitable assumptions, the existence of a random equilibrium distribution is established. Furthermore, a numerical scheme to compute the random elastic traffic equilibrium distribution is presented. At last, a numerical example is provided.

References [1] A. Barbagallo, S. Guarino Lo Bianco, A random elastic traffic equilibrium problem via stochastic quasi-variational inequalities, *Commun. Nonlinear Sci. Numer. Simulat.* 131 (2024) 107798.

2 - Fan-hemicontinuity for the gradient of the norm in several reflexive Banach spaces

Marcel Bogdan

The present study approaches variational inequalities governed by the perturbed operator generated by the energy of the mathematical pendulum. It was proved recently Fan-hemicontinuity for the gradient of the norm defined on its scalarly-positive, closed convex subdomain of a Hilbert space. The aim of the present study is to establish whether or not the positive result obtained for Fan-hemicontinuity can be extended to an arbitrary reflexive Banach space. In this matter it is natural to consider the duality map and its topological properties. Based on weak-weak sequential continuity of the generalized duality map, the property above holds on the discrete spaces of sequences with power p summable and does not hold on the Lebesgue spaces of functions with power p integrable, (p not equal to 2), thus restricting the space setting where weak compactness results are applicable.

3 - Dynamic distributed gradient method for strongly monotone variational inequality problem over the common fixed-point constraints

Narin Petrot

In this talk, we introduce a dynamic distributed conjugate gradient method designed to solve the strongly monotone variational inequality problem across the fixed-point sets intersection of firmly nonexpansive operators. Our method enables the independent computation of a firmly nonexpansive operator alongside a dynamically updated weight at each iteration. This approach aims to enhance the convergence rate of the algorithm by adjusting control factors for each iterative step. By imposing suitable control conditions on relevant parameters, we establish the strong convergence of the iterates towards the unique solution of the variational inequality problem under consideration. Additionally, we conduct numerical experiments and analyze key observations by applying this model to address image classification challenges using support vector machine learning techniques.

Pairwise comparisons and preference relations 4

Stream: Multiple Criteria Decision Analysis

Invited session

Chair: *Matteo Brunelli*

Chair: *Konrad Kulakowski*

1 - My Part is Bigger than Yours! A Proposal for a Consensus Finding Model in a Team of Peers

Konrad Kulakowski

Quite often, scientific papers are the result of collaboration among many researchers. Each researcher focuses primarily on their part of the work, having different ideas about the parts provided by others. It leads to overestimating one's contribution to the research and underestimating the contribution and importance of others. In addition, those whose contribution to the study is relatively significant have a better understanding of the value of the work of the other team members. Therefore, participation is often presented as a verbal description of the work. Unfortunately, this is insufficient when the need is to distribute the reward fairly (e.g., a monetary bonus) for the achievement. In the work, we propose a group decision-making method that establishes some compromise numerical ranking based on pairwise comparisons of alternatives. The model will, on the one hand, consider all stakeholders' opinions and, on the other hand, will give these opinions the right weight. The presented model can be used in many situations where there is a need for proper reward distribution, and the rewarded team wants to avoid entrusting the reward distribution to one individual.

2 - Comparative Insights: Untangling Blockchain Enablers in Traditional vs. Electric Vehicle Manufacturer

Avinash Chauhan, M Vimala Rani

This study conducts a comprehensive comparative analysis of blockchain technology's impact on traditional automotive and electric vehicle (EV) manufacturing sectors, focusing on transparency, security, efficiency, trust, compliance, sustainability, innovation, and customer satisfaction. It utilizes Multiple Criteria Decision Making (MCDM) methods such as AHP and TOPSIS, along with TISM and MICMAC methodologies to develop the conceptual framework and relationship. In traditional automotive manufacturing, blockchain enables enhanced supply chain transparency, ensuring traceability of components and materials, thus improving compliance and fostering trust among stakeholders. This transparency enhances collaboration and streamlines operations. For EV manufacturing, blockchain facilitates lifecycle management of critical components like batteries, optimizing usage, monitoring performance, and ensuring responsible disposal. It also integrates renewable energy sources, promoting sustainability and clean energy innovation. The analysis provides guidance for decision-makers in both sectors to tailor blockchain strategies, unlocking benefits such as transparency, security, efficiency, stakeholder collaboration, and sustainability throughout the supply chain. Embracing blockchain technology empowers manufacturers to navigate challenges and capitalize on opportunities, fostering a more resilient, efficient, and sustainable automotive industry.

3 - Multicriteria Product Prioritization and Classification Methods to Support Production and Inventory Decisions

Murat Kaya

In this study, we propose novel multicriteria product prioritization and classification methods that use criteria from different functions of a manufacturing firm. We transform the scores for each criterion using a quantile transformer. In the prioritization study, the goal is to choose products for pre-build inventory and cycle-stock inventory. Criteria weights are determined with the Analytic Hierarchy Process (AHP) approach. In the classification study, the goal is to develop customized production and inventory policies for different groups of products. To this end, we use Principal Component Analysis (PCA) and Fuzzy C-Means (FCM) clustering. We illustrate the use of the methods with two case studies from a leading tire manufacturer. The methods are transparent and easily understood by company managers. Being structured, data-based as well as flexible, these methods can ease the decision burden on managers, and contribute to quick and well-tailored operational decisions.

4 - A Multicriteria Framework for Assessing Digital Merchandising on Web and Mobile Equipment

Astrid Oddershede, Martin Montalva, Victor Olivares, Luis Quezada

This paper presents a framework for assessing digital merchandising on web and mobile equipment. Making a digital strategy to sell products online a success, is a great challenge. It involves evaluating various aspects related to how products are presented and sold online. Depending on the product, one can develop personalized actions for each type of consumer who visits the site, based on their personal interests and demographic data, to give greater relevance to the most recent articles that have been published on the website, or adapt your ecommerce to new trends and customer behavior. An empirical work has been done based on expert judgements for identifying dimensions' aspects related to products presentation online sales in order to obtain cost-effectiveness. The study provides a basis for setting priorities formulating a Multicriteria decision making model.

Decision Support in the Public Sector and Policy Making

Stream: Decision Support Systems

Invited session

Chair: Nikos Tsotsolas

1 - The comparison of social protection: evaluating collective agreements in public procurement using AHP.

Pietro Bonifaci, Matteo Attanasio, Sergio Copiello, Edda Donati

In the awarding of public contracts, Italian contracting authorities are required not only to evaluate offers but also collective agreements applied to the workers of the participating undertakings. Until the innovations prompted by NGEU, the evaluation of contracts took into consideration the salary only. If it differed significantly from the values reported in tables published by the Ministry of Labour, the prospective contractor was excluded from the tender. A recent reform of the Italian Public Procurement Code introduces an assessment of the overall protection system guaranteed by the specific collective agreement applied to employees engaged in the execution of the contract. The contracting authority must therefore evaluate which of the contracts applied by competitors are equivalent by considering social aspects that are sometimes not directly quantifiable (maternity protection, sick leave, etc.). We propose the use of AHP to support the decision-making process of contracting authorities in the field of social protection, to increase transparency of the process, to guarantee effective protection of workers, and to reduce litigation risk. AHP is chosen for its ease of use and for being already widely applied by contracting authorities in the selection of the most economically advantageous tender. AHP is tested on a case study in which stakeholders directly taking part in collective bargaining (trade unionists, associations, etc.) are involved in the assessment process.

2 - Decision support system for district magistrate

Rajat Goyal, Sanjeev Govindrao Deshmukh, Nomesh Bolia

We can only function as a society with effective public administration. Without public administrators, a government would be unable to function. The responsibilities of public administrators are challenging. India, a nation of immense diversity and cultural richness, stands as a testament to the resilience of democracy and the challenges it faces in managing its vast and complex administrative system. With twenty-eight states and eight union territories catering to almost 1/6th of the world's population, India's public administration system is an intricate network of structures, processes, and institutions. Each Indian state is divided into smaller administrative entities called districts. Each district is managed by an Indian Administrative Service (IAS) officer known as a District Magistrate (DM) or District Collector (DC). DM is one of the key authorities ensuring that the district's administration runs smoothly and efficiently. With different duties and tasks, the DMs are overburdened and overworked. As a result, the Decision Support System (DSS) is essential for facilitating daily operations and significantly enhancing the productivity of DMs. This study aims to comprehensively analyze the challenges faced by the district administration in India and to answer how a decision support system helps DMs make decisions effectively and improve quality and productivity.

3 - Multicriteria Decision Making for Health and Life Insurance Selection in India: A Comprehensive Analysis

Prashant Barsing

This research investigates the complex landscape of health and life insurance selection in India through the lens of multicriteria decision-making (MCDM). With the burgeoning population and diverse healthcare needs, the insurance sector plays a pivotal role in safeguarding individuals against unforeseen health crises and securing the financial future of their dependents. The study aims to develop a robust

decision-making framework that integrates multiple criteria to guide individuals in making informed choices regarding health and life insurance policies. The research methodology involves a thorough analysis of various factors influencing insurance decisions. A comprehensive literature review is conducted to understand consumers' preferences and challenges in the Indian insurance market. The MCDM approach is employed to synthesize the collected data and derive a hierarchical model of decision criteria. The weights assigned to each bar are determined through pairwise comparisons, reflecting the relative importance of factors influencing insurance choices. The research aims to provide a decision support system to guide individuals in selecting insurance plans. The findings of this study are expected to contribute to the existing body of knowledge on insurance decision-making in India, offering valuable insights for both consumers and insurance providers. The research aims to enhance the overall efficiency and effectiveness of India's health and life insurance industry.

Practical Skills: Knowledge-Sharing Tutorials - 2

Stream: Making an Impact
Invited session

Chair: Michele Quattrone

Chair: Andreas Schmitt

1 - Practical Skills: Knowledge Sharing Tutorial -2-

Making An Impact, Michele Quattrone, Andreas Schmitt

Expand your skills with these two 45' practical sessions: Make Easy Changes, Make Changes Easy: A Tutorial On OR Coding Quality; followed by Tricks From The Trade For Large Scale Optimisation.

(i) Make Easy Changes, Make Changes Easy: A Tutorial On OR Coding Quality (Michele Quattrone, Air Liquide) The implementation of well-thought-through quality strategies on the software lifecycle is becoming a requirement for many software developments, even for the early mock-up/prototyping phases. In this 45-minute tutorial, backed with a practical example, we will discuss together how our coding can benefit from this strong push, and what we can cherry-pick from hyping buzzwords such as DevOps, Continuous Integration, Continuous Deployment, MLOps...in practice!

(ii) Tricks from the Trade for Large-Scale Optimization in a practical context (Andreas Schmitt, Zalando SE) Have you had to face up to optimization challenges, where you have had to develop and deploy heuristics in order to implement models into production environments? This session will use the speaker's experience of a successful application as a starting point for discussion.

Practical optimization problems often quickly increase in scale and complexity, necessitating tailored solution approaches. Our talk describes heuristics designed to work along-side a Lagrangian decomposition method, leading to almost-optimal solutions. These have been developed in the context of the frequently applied 'predict-then-optimize' paradigm, more specifically for markdown pricing strategies in the online fashion industry. We present empirical evidence for the heuristics' effectiveness, drawing on pricing applications at Zalando SE.

This exposition will serve as a starting point for discussions: Participants will be encouraged to explore questions such as: What are your experiences with similar optimization challenges? How do you approach heuristic development in their work? What are effective approaches for deploying such models into production environments and measuring their impact?

■ WB-47

Wednesday, 10:30-12:00 - Room: 50 (building: 324)

MCDA in energy

Stream: Multiple Criteria Decision Analysis
Invited session

Chair: Janusz Granat

1 - Integrating multicriteria analysis with advanced data analysis methods

Janusz Granat

Data-driven multicriteria analysis is a challenging research area integrating data analysis from two sources: first, raw data used for development of a model or a set of alternatives, and second, the data provided by the model simulation or its interactive analysis. The presentation focuses on the second issue.

First stage of interactive multicriteria decision analysis generates several sets of solutions. The corresponding data can be then analyzed for supporting selection of a final decision, as well as providing information guiding specification of parameters of the user preferences in further interactions. Applying data analysis in the process of multicriteria analysis significantly improves the decision-making process and reduces the required computation time. Use of the cluster-based surrogate in discrete decision-space helps in reducing the discrete decision space dimension, and thus the computational resources needed for solving the underlying optimization tasks.

The effectiveness of the approach is illustrated by analysis of an energy model supporting decisions of a system operator of an onshore wind farm equipped with a hydrogen energy storage. The objective is to maximize the cumulative profit by deciding on: (1) a constant hourly amount of electricity to be delivered, (2) configuration of the storage system components, and (3) control of flows to/from the storage to deal with the variable renewable energy generation.

2 - Evaluating Sustainability in Renewable Energy Systems: Introducing a Novel Fuzzy Multi-Criteria Distance to Ideal Solution Approach

Sepehr Hendiani, Grit Walther

Sustainable development strongly requires a shift away from fossil fuel-based energy systems and toward ones that rely on renewable resources. It is well recognized that the first step in improving sustainability is to evaluate the current degree of sustainability. This research proposes a unique approach for assessing the existing level of sustainability through renewable energy systems (RESs) using multi-expert multi-criteria decision-making based on a distance to ideal solution method under interval type-2 fuzzy information. The proposed method highlights underperforming sustainability components according to the linguistic data collected from experts, which helps decision-makers identify the obstacles to sustainable growth. The proposed approach may make it easier to create global sustainable development policies and plans that are more successful. This may be achieved via improving the quality of experts' linguistic assessments and by offering a thorough grasp of the sustainability of RES around the globe.

3 - Renewable Fuels in Transport: An Analysis of Market Development Barriers

Ali Ebadi Torkayesh, Sepehr Hendiani, Grit Walther, Sandra Venghaus

Aligned with the EU, Germany aims to reduce its GHG emissions by 65% compared to the 1990 levels, with the objective of reaching climate neutrality by 2045. While most sectors have achieved a notable decline in GHG emissions, measures to reduce emissions in the transport sector have proven largely insufficient. A key challenge for decarbonizing the transport sector remains the dominating role of fossil fuels in the current GHG emissions level. Thus, the adoption of renewable fuels is of high significance for meeting the climate targets. Renewable fuels, e.g., power-to-x, advanced biofuels, hydrogen are supported by the Renewable Energy Directive III, where the objective is to meet a minimum share of 5.5% in European energy consumption

in the transport sector by 2030. Despite the advantages of renewable fuels, various economic, environmental, technical, regulatory, and social challenges exist to their adoption and diffusion. To investigate the importance of the barriers and their interactions from a system perspective, an analytical approach is developed based on the decision making trial and evaluation laboratory, K-means algorithm, the maximum mean de-entropy algorithm, interpretive structural modeling, and a ranking multi-criteria decision analysis method with Type-2 Neutrosophic Numbers. Insufficient renewable energy policies and lack of coordination in the supply chain are identified as the main system barriers.

Wednesday, 10:30-12:00 - Room: 60 (building: 324)

DEA applications in transportation

Stream: Data Envelopment Analysis and its Application
Invited session

Chair: [Chixiao Lu](#)

1 - A novel two-stage network DEA approach to estimate production efficiency of the bus transportation system. *Shivam Kushwaha, Anand Venkatesh*

In this paper, we utilize the internal structure of the bus transportation system's to assess its production inefficiencies. Specifically, we exploit information about linkages of resources across departments and identify inefficient sub-activities within the production system. Our proposed framework employs a two-stage network DEA framework to assess the overall production efficiency of the bus transportation system. Since departments of the bus transportation system share limited resources, game-theoretical approach has been employed for decomposing production efficiency to estimate optimal efficiency estimates for each division. To demonstrate the practical application of our approach, we implement it in the context of the Indian bus transportation system. Finally, we conclude by discussing the policy implications of our research and offering recommendations for managers to enhance overall production performance.

2 - Input congestion assessment in the North Adriatic ports *Mozhgan Mansouri Kaleibar, Evelin Krnac*

Recognizing the critical role that ports play in promoting trade and economic expansion worldwide, port authorities are actively seeking strategies to reduce inefficiencies and improve port operations. The seaports along the northern Adriatic are an essential part of the European transport network. An important approach to reduce inefficiencies in the ports is to assess and eliminate port congestion in order to minimize operational bottlenecks. Data Envelopment Analysis (DEA), a widely used technique for assessing decision making units (DMUs) in different sectors, is also suitable for measuring congestion in individual units. In this study, a one-step DEA model is used to determine the efficiency scores and congestion of ports in the northern Adriatic in the years 2020-2022, allowing for a simultaneous assessment of inefficiency and congestion. The results show which ports are confronted with the problem of inefficiency and congestion during the period under investigation. The analysis provides these ports with insights for more precise and effective resource allocation and coordination.

3 - Evaluating eco-efficiency under dynamic network setting for passenger road transportation: A case study of State Road Transport Undertakings in India *Sanjeet Singh, Saransh Tiwari*

State Road Transport Undertakings (STUs) in India are state government-operated transport services that connect various landscapes and isolated mountainous regions across the nation, serving as

a crucial catalyst for improving public transit. These organizations are driven by a strong sense of social responsibility. As an illustration, they function in locations with poor income generation to cater to the public. Hence, it is necessary to regularly assess their performance and consistently make attempts to make necessary adjustments. Road transport has a significant role in the economy, but it also contributes significantly to energy consumption and environmental damage, particularly through air pollution. STUs, which run on high-speed diesel, emit air pollution as a byproduct of fuel combustion. This has sparked worries over its adverse effects on climate change and the long-term viability of ecosystems. The current body of research on performance evaluation of passenger transportation systems fails to consider the fundamental structures of the transportation process and instead approaches it as an opaque entity. As a result, it is unable to accurately determine the exact reason for inefficiencies, which makes it challenging to adjust in the complex transportation process. Prior research on STUs has not considered the possible negative impacts on the environment.

4 - The pitfall of virtual exterior projection points in unified Non-Radial Two-Stage Network DEA and its duality: An Empirical Study on Railway industry in Europe *Chixiao Lu, Ali Emrouznejad*

As a natural monopoly transportation approach, the railway service has gained increasing attention from the European Union. Hence, a comprehensive performance analysis system is needed to urge infrastructure managers to reduce costs. Two-stage network (2SN) Data Envelopment Analysis (DEA) is widely used as a productive efficiency analysis technique in railway industries' managerial decision-making processes. However, the conventional 2SN DEA models are vulnerable to biased outcomes when the generated virtual projection point is an exterior point. Specifically, given the inputs-outputs Production Possibility Set (PPS) in a 2SN system is unknown, the conventional approach identifies the virtual exterior projection point by integrating the inputs-intermediates and intermediates-output PPSs. In this paper, unified non-radial graph models in both the slack-based scheme and the Russell-efficiency scheme are proposed to solve the issue of exterior projection points. We also apply the dual transformation to discuss the shadow price of inputs, outputs, and intermediates through the multiplier model. We apply the proposed novel approach to the dataset regarding European Railway industries. Our approach provides a comprehensive efficiency analysis from both Investment and Operations perspective. The adjusted projection points in our DEA model also provide an applicable benchmark to support the decision-making process.

Wednesday, 10:30-12:00 - Room: M1 (building: 101)

Flow shop scheduling problems

Stream: Lot Sizing, Lot Scheduling and Production Planning
Invited session

Chair: [Yiannis Mourtos](#)

1 - A bi-objective distributed permutation flowshop scheduling problem with factory eligibility and qualification options *Martin Schönheit*

The competitiveness of manufacturing companies, especially those with multiple plants, is increasingly determined by their operational efficiency and agility. A challenging issue when considering multiple factories is the optimal allocation and scheduling of orders, which is further complicated by the lack of tools and personnel that limit the ability to process an order in each factory. Thus, this paper contributes by solving a bi-objective distributed permutation flow shop scheduling problem with eligibility constraints focusing on minimizing total cost and total weighted tardiness. For the first time, factory-dependent due dates and qualification options through tool transfer to an initially

ineligible factory are investigated. In addition, emission costs are considered alongside transfer, delivery, and production costs to promote a holistic problem view. Extensive computational experiments are used to analyze the effects of varying the strictness of factory eligibility constraints, changes in product and tool weight factor levels, and an increase in the emission price. The results illustrate the critical role of transportation in distributed scheduling and highlight the benefits of factory qualification in terms of on-time order delivery and cost minimization. Finally, the integration of factory eligibility constraints and factory-dependent due dates strengthens the robustness of the management implications by better reflecting industry constraints.

2 - Multiobjective flowshop with additional resources during setups

Juan Camilo Yepes Borrero, Federico Perea, Justo Puerto

This work investigates the flow shop scheduling problem with setup requirements and additional resources for setups from a multi-objective perspective. The setups required on machines after processing a job depend on the sequence, as well as the resources needed to perform them. The two objectives studied are minimizing the makespan and minimizing the additional resources used. Exact algorithms and meta-heuristics are proposed to solve the problem. To evaluate the resolution methods, sets of non-dominated solutions obtained by each method are compared.

3 - Exact methods and (meta-)heuristic solution methods for the Hybrid Flexible Flowshop problem

Stavros Vatikiotis, Ilias Mpourdakos, Dimitrios Papathanasiou, Yiannis Mourtos

Modern manufacturing keeps on introducing research challenges in terms of both problem structure and instance size. The Hybrid Flexible Flowshop (HFFS) represents a setting where a set of jobs needs to be processed on a set of sequential stages, each containing a different number of parallel (and typically identical) machines; each job will be processed at one machine at a time and it is possible to skip some stages. Additional structure is introduced by i) machine-dependent transportation times between the consecutive stages, ii) limited capacity buffers on the entry and on the exit of either each machine or each stage and, iii) two different types of renewable resources - the first responsible for the transportation of jobs between stages and the second affecting job processing in specific machines. To handle the above on instances of several hundred of jobs, while sustaining the ability to calculate optimality gaps, we examine both exact methods (MILP and CP) and (meta-)heuristic algorithms. Since exact methods commonly struggle with large instances, we examine also whether MILP-based and CP-based formulations can solve parts of the problem or sequentially handle parts of the instance. These components are combined with constructive heuristics and evolutionary schemes to offer a method versatile in the sense of offering multiple solutions for diverse time horizons. The results of the methods are compared in computational terms on both benchmark and real-life instances.

4 - Balancing and scheduling human-robot collaborated assembly lines considering cycle time, energy costs, and ergonomic risks

Amir Nourmohammadi, Masood Fathi

The recent Industry 4.0 trend, followed by the technological advancement of collaborative robots, has convinced many industries to shift towards semi-automated assembly lines with human-robot collaboration (HRC). Moreover, moving towards the human-centric and resilient industries proposed by the Industry 5.0 vision, the increasing use of HRC-based collaborative assembly systems is anticipated in the near future. In the HRC environment, robot agility can support human skill upon efficiently balancing and scheduling tasks among the stations and operators. However, in this attempt, the cycle time (CT), the total energy cost (TEC) of robots, and the total ergonomic risks (TER) of humans are among three conflicting objectives. Thus, this study deals with the balancing and scheduling of HRC lines where a trade-off between CT, TEC of robots, and TER of humans is sought. A mixed-integer linear programming model is proposed to formulate the problem. In addition, a multi-objective optimization approach based

on ϵ -constraint is developed to address a case study from the automotive industry and a set of generated test problems. The computational results show that promising Pareto solutions in terms of CT, TEC, and TER can be obtained using the proposed approach.

■ WB-50

Wednesday, 10:30-12:00 - Room: M2 (building: 101)

Retail Distribution II

Stream: Retail Operations

Invited session

Chair: *Rob Broekmeulen*

1 - Optimal Design of Walmart's Grocery Import Network

Foad Iravani, Vivek Tomar, Sai Rajesh Mahabhashyam

Walmart's mission is to be the number one food destination in America. A critical driver of this mission involves creating an efficient and flexible grocery supply chain. We present an optimization model for Walmart's grocery import network, designed to determine the optimal locations of import facilities, inbound flows of products from overseas suppliers, and outbound flows to Walmart's distribution centers. The model enables us to design the imports network for both fresh and freezer items. We describe how the solutions from this optimization model have shaped Walmart's strategy for direct importation of groceries, saving billions of dollars, and exploring new opportunities for creating efficiency in Walmart's overall grocery network.

2 - Last-mile fulfillment in Omnichannel Retail: A combined allocation and routing problem

Rakesh Venkitasubramony

Integrating multiple channels and delivering a seamless experience to customers in an Omnichannel setting presents a set of interesting and challenging problems in fulfillment. In particular, when an order needs to be delivered to a customer's home, a delivery executive can pick up the items from any of a set of stores which are in the vicinity (ship from store), or from any other node in the distribution network like a regional warehouse (order allocation). We develop a combined order allocation and routing problem for a retailer who has a multi-tier distribution center network and a set of stores serving customers in a city. We consider real-world requirements like minimum inventory requirements at stores and service time for customers. Solutions are presented for generated test data. Some real-world policies (like batching windows) are discussed, and future research opportunities are identified.

3 - Simulation-based Multi-objective Optimization for Fleet Resource Planning in a Convenience Store Supply Chain

Thai-Young Kim, Benjawan Sopun

Fleet planning is a key success factor of retail management in the convenience store industry where a wide range of goods are replenished on a daily basis. The operational challenge in this industry is to decide the size of transport equipment - reefer truck and dry truck in an optimized manner. The idea to get some flexibility in the fleet pool decision is that the reefer truck can be used as a dry truck if the temperature control is disabled with limited cost increases. In this study, a simulation approach categorized as Digital SC twins is selected to demonstrate the benefits of increasing compatibility by opting for a mixed-truck policy including the optimal fleet size and timeline. The study optimizes the mixed vehicle in terms of fleet maximizing the service level while minimizing costs by applying the proposed policy. To set up a real-life simulation baseline, a convenience store supply chain in South Korea was modeled with some operation parameters. Initial simulation revealed the impact of time windows on reducing the number of vehicles used in standard operation. The second experiment investigated the effect of reefer trucks ratio to dry trucks under each time window standard operation. The finding is that the optimized fleet planning enables

the supply chain to maintain the same level of on-time delivery even with fewer vehicles. It can effectively resolve the issue of delayed delivery due to insufficient capacity while reducing total costs and travel distances.

4 - Lateral Trans-Shipments within an Apparel Retail Chain

Waldemar Kaczmarczyk

In the middle of the season, apparel retail chains can increase sales by trans-shipment of unsold commodities between different stores. Planning of such an operation may be described with the help of a many-to-many transportation model. However, the product and its size variety are tremendous, while the amount of any product in a specific size that any store may send to another one is small. In the considered company, all shipments should go directly from one store to another (drop-ship) rather than through the central warehouse. A forecast of the demand is unavailable, first, because the product collection changes very often, and second, because the sales of the same product differ significantly among different stores. Therefore, decisions must be based on rules proposed by managers and verified over several seasons by experimentation. Moreover, the trans-shipment plan must keep employees' workload acceptable. This paper presents the general concept of the trans-shipment approach, mixed integer programming models of the considered problem, and the proposed hierarchical planning approach.

Railway Traffic Management

Stream: Public Transport Optimization
Invited session

Chair: Dennis Huisman

1 - Realistic assessment of rail traffic management optimization: a demand-supply simulation framework

Johan Victor Flensburg, Bianca Pascariu, Gregory Marlière, G. Sfeir, Federico Naldini, Filipe Rodrigues, Paola Pellegrini, Carlos M. Lima Azevedo

Our research addresses the need for a realistic assessment of rail traffic management algorithms. We introduce a modular framework integrating demand and supply dimensions for algorithm evaluation. Our approach incorporates passenger simulation via an application programming interface (API) in the commercial rail traffic simulator OpenTrack, enabling realistic route choice modeling and passenger rerouting based on observed choices and traffic conditions. Trains are realistically simulated in OpenTrack, and historical distributions of traffic perturbations are applied via the API. When train delays increase, the API triggers passenger rerouting: depending on the current and planned traffic evolution, passengers decide whether to stick to their original plan or choose a different option. This mimics realistic decisions, where passengers react to updated traffic information. The proposed framework allows for the closed-loop assessment with a traffic control optimization algorithm, ensuring practical feasibility. We validate the framework using diverse scenarios in a Copenhagen suburban rail network, exploring variants of optimization algorithms with objectives including train delay minimization and passenger delay considerations. Our proposal represents the first comprehensive framework integrating passenger behavior and realistic rail traffic simulation, enhancing the evaluation of traffic management algorithms.

2 - Track discretisation in railway traffic rescheduling models for next-generation distance-to-go signalling

Nina Versluis, Paola Pellegrini, Egidio Quaglietta, Rob Goverde, Joaquin Rodriguez

In case of disturbed railway operations, traffic management can apply rescheduling measures to resolve conflicts while minimising delay

propagation. This can be optimised by conflict detection and resolution (CDR) models. Usually based on alternative graph or mixed integer linear programming (MILP) formulations, existing models mostly refer to conventional signalling systems in which the track is discretised into blocks. Only at block entries, trains can receive a brake indication. Hence, train separation distances are based on a number of blocks. With the implementation of continuous braking curve supervision in distance-to-go (DTG) signalling systems such as the European Train Control System (ETCS), train separation is based on absolute braking distances. Consequently, an explicit relation between speed and train separation is required in CDR models for DTG signalling. Recently, we enhanced the CDR model RECIFE-MILP to DTG operations. The enhancements relate to track discretisation and speed-dependent train separation. In this research, we investigate the effect of track discretisation granularity on the performance of the enhanced model for next-generation DTG signalling systems: ETCS Level 3 Fixed Virtual Block and Moving Block. The performance is assessed regarding total delay and rescheduling decisions. The results indicate that, depending on the track and traffic scenario, a finer granularity can lead to different rescheduling decisions due to shorter train separation.

3 - Integrating Reinforcement Learning methodologies into a generic CDCR Heuristic to effectively resolve occupancy conflicts at railway nodes in real-time.

Arturo Crespo Materna, Cedric Steinbach, Shanqing Chai, Keren Zhou, Andreas Oetting, Hendrik Speh

This contribution presents a novel approach to enhance the real-time resolution of occupancy conflicts at railway nodes by integrating Reinforcement Learning (RL) methodologies into a generic Conflict Detection and Conflict Resolution (CDCR) heuristic. Given the intricate nature of railway systems, the occurrence of stochastic events cannot be avoided. In this context, conflicting operations between train journeys must be resolved. These conflicts are harder to resolve within nodes than in lines due to the larger number of possible resolution combinations. The proposed approach foresees the integration of RL into an existing CDCR heuristic approach for resolving occupancy conflicts in nodes. The generic CDCR Heuristic provides a baseline for identifying and resolving conflicts, while RL enriches the system's intelligence by providing real-time feedback learned from historical data. The resulting hybrid approach facilitates adaptive decision-making, optimizing train movements, and minimizing the overall delay in the system. The integration of RL within the existing CDCR heuristic aims to enhance the system's efficiency and effectiveness, ultimately improving the overall efficiency of railway operations. The proposed approach is evaluated in a real-world scenario, demonstrating its potential to enhance real-time schedule adjustments by providing robust, optimized solutions to occupancy conflicts.

Parallel Optimization and Scalability

Stream: Combinatorial Optimization
Invited session

Chair: Guido Schryen

1 - Performance Analysis of MIP Solver Software on Various Hardware Architectures

Willi Leinen, Andreas Fink, Philipp Neumann

There is still much room for exploiting high-performance computing hardware to solve hard combinatorial optimization problems, such as those in logistics and scheduling. However, the difficulty of partitioning and organizing the work of typical MIP tree-search algorithms limits the impact of approaches aimed at massive parallelization, even though the use of large computing clusters or GPUs has considerable potential in theory. As a result, MIP solvers are frequently used on single CPUs with limited shared-memory parallelization via multi-threading; however, even in these situations it is often not worthwhile to use more than a few cores. This usually involves procedures that

take advantage of performance variability by concurrently running different configurations in parallel. To gain a deeper understanding of the performance of available MIP solver software in these multi-threading scenarios, we conduct strong scaling experiments to analyze the influence of hardware characteristics (such as processor type, number of cores, clock speed, cache, RAM) and performance variability. We provide insights into performance optimization in terms of runtime, speedup, cost, and power consumption.

2 - Minimizing service levels in the stochastic parallel machine scheduling problem

Hiba Yahyaoui, Stéphane Dauzere-peres

In this work, we address the parallel machine scheduling problem where processing times are stochastic. The objectives to maximize are the makespan service level, i.e. the probability that the makespan is smaller than a given threshold, and the due date service level, the (weighted or not) sum of the probabilities that the jobs are completed on time. Mathematical models for both objectives, that rely on the generation of scenarios and on positional binary variables, are presented. Heuristics are also proposed, and numerical results are discussed

3 - Metaheuristics for Optimization on Graphs

Tatjana Davidović, Dragan Stevanović, Predrag Djordjevic, Robert Doža, Luka Radanovic, Marko Milenkovic, Milica Anđelic

Optimization problems on graphs involve the search for graphs of a given size that minimize or maximize a certain invariant or a combination of invariants. These problems are usually NP-hard and the exhaustive enumeration of all possibilities is not acceptable. Efficient dealing with these problems can help theoreticians to get some useful hints and make analytical proof out of these results. Computer-assisted proofs are common in the graph theory for a while now. Several dedicated software packages have been developed, such as AutoGraphX (<https://www.autographix.ca>), newGraph (<https://www.mi.sanu.ac.rs/newgraph/>), PHOEG (<https://phoeg.umons.ac.be/phoeg>), to mention a few. They are, however, too general and in some cases could require unacceptably long CPU time to provide useful results. Another popular approach is to develop metaheuristic tailored for each particular optimization problem. We illustrate the application of Variable Neighborhood Search (VNS) metaheuristic to Spectral Reconstruction of Graphs and Maximization of Spectral Radius of Threshold Graphs. The proposed algorithms are tested on a representative set of test graphs. Conducted experimental evaluation shows the superiority of the proposed approach over the application of dedicated software. The work has been partially supported by the Scientific Fund of the Republic of Serbia, Grant LZWK.

4 - Deriving Upper and Lower Bounds with Stochastic Dynamic Programming for Request Acceptance and Scheduling Decisions under Uncertainty

Marvin Caspar, Konstantin Kloster, Oliver Wendt

Sophisticated decision-making becomes necessary when weighing the value of accepting and simultaneously scheduling or rejecting a random incoming request now versus the value of waiting for another request in the future. This work proposes the Dynamic Request Acceptance and Unsplittable Scheduling Problem (DRAUSP), which considers a single resource with a given capacity over multiple homogeneous time slots. During each decision period within a fixed time horizon, a single random request arrives that demands capacity for some consecutive time slots and yields positive revenue if accepted. The objective becomes to accept or reject the incoming requests and, if accepted, to schedule them into available time slots to optimize the revenue collected over the time horizon. We use a Stochastic Dynamic Programming (SDP) algorithm to optimize the DRAUSP, which we model as a Markov decision process. In addition, we present a dimension compression technique to compute upper and lower bounds using SDP. Our computational study shows that we can derive appropriate bounds for some DRAUSP instances in reasonable computational time. Moreover, we conclude that basic heuristics, such as First Come First Serve, are insufficient to handle the complexity of DRAUSP and that more sophisticated heuristics are necessary to obtain adequate results.

Chair: *Michaela Chocholatá*

1 - Transition of the heating sector in a large city: simulation of scenarios with a digital twin

Maik Günther

In the 'Model Munich', Stadtwerke München has collected spatial data on buildings, parcels of land and building blocks. This digital twin of the City of Munich is primarily used to answer questions related to the transition of the heating sector. Therefore, building-specific heat demand, utilized energy sources and technical building properties, but also regionally resolved supply potentials for groundwater heat pumps, air heat pumps, heating networks, etc. are included. Moreover, the 'Model Munich' is connected to the bottom-up simulation model Invert/EE-Lab, which employs a nested logit approach for building-specific calculations of long-term scenarios regarding the change in heating systems and renovation activities. A specific application of the 'Model Munich' is municipal heat planning. In 2021, Stadtwerke München agreed with the City of Munich to utilize this model for municipal heat planning. Within this collaboration, numerous simulation runs were conducted using Invert/EE-Lab, from which valuable insights could be gained. This contribution provides an overview of the architecture of the 'Model Munich'. In addition, results of the simulation runs are presented, aiming to achieve climate neutrality by no later than 2045 in accordance with the German Heat Planning Act.

2 - Enhancing User Comfort in Smart Buildings through CO2 Forecasting and Operational Optimization

Albert Farriol Salas, Lucia Igualada, Tomas Montes, Manel Serrano Borja

This study introduces an optimal operational model for a smart building, showcasing the integration of indoor Carbon Dioxide (CO₂) forecasting. The study presents an hourly operational model that encompasses the Heating, Ventilation, and Air conditioning (HVAC) system, electrical storage (ES), and Light-Emitting Diode (LED) lights, along with the utilization of photovoltaics (PV). The first objective is to employ a Long Short-Term Memory (LSTM) neural network to predict indoor CO₂ concentrations and identify hours when these concentrations exceed the healthy threshold. Subsequently, the operational model is presented to ensure optimal energy usage, flexibility to selectively activate or deactivate the entire HVAC system during hours when forecasted CO₂ levels surpass unhealthy thresholds. This proactive measure aims to prevent the escalation of indoor CO₂ levels. By combining CO₂ forecasting with operational optimization, this study contributes to enhancing the sustainability and performance of smart buildings while prioritizing the well-being of occupants. Additionally, the model ensures that optimal lighting levels are maintained at all times without compromising the visual comfort of building occupants. These algorithms and models have been developed in the context of the Netbuild project (CPP2021-009031), where the developments will be implemented in a real smart building located in Viladecans, Spain.

3 - Low carbon and greener Europe priority as a challenge for heating in Slovakia

Michaela Chocholatá

Low carbon and greener Europe priority has also been a great challenge for heating of households. In Slovakia, the recent results of the 2021 Housing Census showed e.g., that up to 66.22% of households are heated with gas, up to 21.32% with solid fuel and 4.48% with electricity. Various subsidy mechanisms were introduced by government to support the transition towards low-emission energy sources used for heating. Among others, a web application "Heating in households a

little differently" was developed in order to make the people in Slovakia more aware of air pollution from domestic heating as well as to show the ways how to improve the quality of air. This paper presents the regional data (for 79 Slovak districts) to show the huge regional differences concerning the heating (solid fuel, gas), but also analyses other regionally unevenly distributed variables with potential impact on the source used for heating. Instruments of exploratory spatial data analysis and spatial econometrics were used for analysis. The results showed that both the spatial autocorrelation and spatial instability were strongly confirmed in case of Slovak districts.

1 - Multi-period line planning for varying railway demand considering stops, frequencies and asymmetric lines

Renate van der Knaap, Niels van Oort, Menno de Bruyn, Rob Goverde

The purpose of the line planning problem in railways is to determine a set of lines with their route, stops and frequency. This line plan is an important aspect of the quality of the service that a railway undertaking (RU) provides to its passengers. For example, it determines which origin-destination pairs are connected by a direct trip or need a transfer between lines. Although the railway demand is varying throughout the day in volumes and directions, the line plan is often constant throughout the day. To better match the supply with this varying demand, we present a mixed-integer linear programming model for multi-period line planning. With this model, we intend to determine a line plan for each period with different demand, that minimizes the generalised journey time (GJT) of the passengers. To meet the varying demand, we allow the model to make changes to the selected routes in the network, the stopping pattern, and the frequency in each period. Furthermore, we include the possibility of having asymmetric lines to deal with spatially unbalanced (peak hour) demand. Although changing the line plan during the day has a benefit for the passengers in terms of reduced GJT, it also comes with costs: RUs must create multiple plans and passengers need to adapt to multiple plans per day. Therefore, the ϵ -constraint method is used to create Pareto optimal solutions. We use Gurobi to solve the proposed model for a case study based on real data of part of the Dutch railway network.

2 - A fast insertion heuristic for demand responsive transport

Richlove Frimpong, Julia Bennell, Rym M'Hallah, Christine Currie

Demand Responsive Transport involves the provision of door-to-door services to customers which allows them to choose their pickup or drop-off times and locations, while sharing the vehicle with other riders travelling along the same route. This is similar to dial-a-ride services, however the aim of this work is to extend this service to the entire population rather than limiting it to customers with mobility issues. To operate such services, the service provider needs to check the feasibility of accepting or rejecting a customer's request and also estimate the cost of offering the journey in real time.

As such, we propose an insertion heuristic which uses iterative search methods and an exact method that uses constraint programming to instantly determine the feasibility of inserting the customer request at a given price whilst anticipating future demand. This will subsequently be combined with a background optimisation algorithm using

mathematics to enhance the effectiveness and efficiency of the proposed routes and schedules across the fleet. We would also discuss how this work fits into a larger project ADROIT, which involves the development of analytical methods for pricing and operating demand responsive transport using Leeds as a case study.

3 - An LNS-based heuristic for optimizing on-demand transportation services in a hybrid mobility system

Soukaina Bayri, Kris Braekers, Yves Molenbruch

Mobility-as-a-Service (MaaS) transforms mobility systems into more flexible and efficient ones by integrating different transportation modes. In this research, the focus lies on the integration of timetabled public transport (PT), dial-a-ride (DAR) services, and walking, allowing passengers to travel by a combination of these three modes. From the perspective of the provider, the exploitation of such a hybrid mobility system leads, among others, to challenging routing and scheduling problems on the operational level. The ultimate aim is to generate efficient real-time solutions in response to all user requests by optimally combining and aligning the available transport modes with each other, while minimizing the operational costs and the total trip times of the users.

Therefore, in this talk, an optimization problem is introduced which involves decisions on the combination of modes for each request and the routing and scheduling of the DAR vehicles. The focus lies specifically on a network in which users commute between a rural and an urban area. A heuristic algorithm based on Large Neighborhood Search (LNS) is proposed. To incorporate the trade-off between the operational costs and service level, a tailored scheduling sub-procedure is presented which minimizes the sum of the users' trip durations for a given route. Lastly, a sensitivity analysis is carried out on small-scale artificial instances gaining more insight into the problem-specific parameters.

4 - Analysis of an on-demand public bus line with demand imbalance during peak hours

Dilay Aktas, Kenneth Sørensen, Pieter Vansteenwegen

In this study, we present an on-demand system in order to improve the efficiency of a single bus line facing a clear demand imbalance during peak hours. The on-demand system aims to increase the efficiency of service by allowing vehicles to take shortcuts between the city center and the terminal given the set of passenger requests known at the time. Passengers indicate their origin, destination, and desired pick-up time through an app or an online platform. Since the passenger requests are explicitly taken into account, each passenger is assigned to a service that serves their origin and destination. This assignment is also communicated to the passengers some time before their desired departure time. Given the practical importance of efficiently optimizing the decisions of this system in a short time, a VNS algorithm is developed. The algorithm decides which shortcuts to take by each bus and in each direction, when to depart from the city center and the terminal, and the corresponding passenger assignments in a matter of minutes. The performance of the system is analyzed under different circumstances.

Chair: Antonio Mauttone

1 - New mathematical modelling for setting frequency of bus transportation

Glaydston Ribeiro, Joyce Caetano, Laura Bahiense, Glaubos Climaco

The Frequency Setting Problem (FSP) represents a key element in transit design, specifically in public transportation operations. It consists of determining the number of departures to meet passengers' demands during a specific period, ensuring the profitability of the companies. However, the FSP also involves different interests that commonly conflict, making the planning of the transportation system complex. When this plurality is not correctly captured, we have an imbalance between demand and supply. So, we are interested in addressing these distinct objectives through a sustainable perspective, with an emphasis on buses.

This research introduces a mathematical model and optimization techniques to improve bus route frequency, minimizing social, operational, and environmental costs. The model comprises a mixed-integer non-linear formulation, and the optimization techniques involve linearization and a heuristic approach, which is based on sequentially solving relaxed mixed integer subproblems and fixing integer variables throughout the process. To validate our proposal, we consider the bus routes connecting the central and oceanic regions of Niterói, Brazil.

The findings suggest that the combined approach is effective in real-world scenarios, enhancing sustainable mobility through optimized fleet allocation according to current demand. The next research steps include creating a Multi-Criteria Decision Method (MCDA) to support operator decision-making.

2 - Dispatch and route control of an urban public transportation system composed of buses with a mixed fleet

José Edgardo Niño Báez

Abstract: In the operation of high-frequency buses, it is important to maintain regularity in the service, reduce user waiting times, and maintain a low cost of operation. A key aspect to achieve this is to dispatch buses at regular intervals and control the interval during the routes, through strategies such as holding buses at stops. In systems where different lines operate that begin their operation at a common terminal, it is usual for buses to remain on the same line each time they arrive at the terminal after finishing a route, which limits the flexibility of the system. In this work, we seek to minimize user waiting times and the operating costs of a bus system by implementing bus spacing strategies at the terminal and a route control strategy to maintain regularity in the service. Our preliminary results show that when it is possible to interline buses in the terminal, waiting times are reduced between 10% and 20% compared to the case without interlining.

3 - Frequency optimization in public transportation with strict capacity constraints

Antonio Mauttone, Agustín Arizti, María E. Urquhart

The problem of frequency optimization consists in defining the number of vehicles per time unit, to operate each line of the system. The inverse of the line frequency is the time interval between consecutive vehicles in the line, which determines the waiting time. Given an available fleet and origin-destination demand data, we seek to minimize the total travel time of passengers, including in-vehicle and waiting components. To evaluate a frequency setting we apply the optimal strategies assignment model, which represents passenger behavior and outputs demand flows over the lines and passenger travel time from origin to destination. The capacity of a line is determined by its frequency and the size of the vehicles which operate the service. In systems operating over capacity, the flows produced by the assignment model exceed line capacity, causing failure to board the vehicles that passengers choose. To avoid this endogenous effect which invalidates the whole model, we propose a frequency optimization model that guarantees sufficient capacity in all lines. This is achieved by including a strict line capacity constraint in a bilevel programming model. After applying a reformulation, we obtain a mixed integer linear programming model which can be solved to optimality for small to medium size cases. We apply the model to a simple toy instance and to a well-known one, taken from literature. Numerical results allow for investigating the usefulness and the limitations of the model.

4 - A Fixed-route Autonomous Modular Public Transit Service

Jane Lin

In this work, we present a proof-of-concept investigation of Autonomous Modular Public Transit (AMPT) at a network scale and compare it with the traditional fixed-route, fixed-vehicle size transit service in terms of total cost, which consists of both agency's capital and operational cost (including energy cost) and passenger time cost. We formulate and solve stylized design models for AMPT on a grid network in a range of demand density scenarios with both homogenous and heterogeneous distributions. The AMPT models explicitly account for pod joining and disjoining (and therefore en-route transfers of passengers) and potential energy savings due to pod train formation (pod platooning), which represent major departures from the traditional transit models in the literature. Numerical results find that AMPT, if designed properly, may save the total cost compared to traditional transit systems thanks to demand responsive pod train capacity, particularly in the low demand scenarios. The cost savings of AMPT are largely attributed to passenger time saving by en-route transfer; the agency cost of AMPT has a mixed picture. The load factor of AMPT generally improves over the traditional transit service. We also show how key parameter values may affect the AMPT costs through sensitivity analysis.

1 - Scheduling AGVs based on partial charging policy to minimize the total tardiness

Mengxin Zhang, Hui Sun

This study addresses a problem of scheduling automated guided vehicles (AGVs), in which a fleet of heterogenous AGVs are used to deliver materials in a flexible manufacturing environment. During the transportation process, the batteries of AGVs can be recharged so that materials are delivered timely to various workstations without interruptions. A partial charging policy which enables flexible management of charging operations is applied. By effectively scheduling transfer jobs and potential charging operations on the AGVs, the objective is to minimize the total weighted tardiness. A mixed integer programming formulation is presented to describe the scheduling problem. A hybrid approach combining variable neighborhood search (VNS) and linear programming is developed to solve this NP-hard problem. VNS is firstly used to schedule transfer jobs on the AGV fleet without considering charging operations, based on which a linear programming model is formulated to determine the best schedule of charging operations on each AGV. Numerical experiments show that the hybrid solution procedure can solve the AGV scheduling problem effectively and efficiently.

2 - The Multi-objective Transit and Car Network Design Problem

Tygo Nijsten, Jan-Pieter Dorsman, Michel Mandjes, Maaikje Snelder, Erwin Walraven

The car is currently the most popular transport mode, due to, among other things, its convenience and comfort. In many urban areas, the resulting high car usage leads to considerable road congestion. On top of this, it goes paired with several negative externalities like noise pollution and greenhouse gas emissions. Therefore, measures to shift towards more sustainable modes of transport, like public transport, may be beneficial. However, several trade-offs may occur, for example, shifting towards public transport might cause higher travel times.

In the literature, it has been proven difficult to take into account all trade-offs in one single objective function. While some research has

been conducted on the multi-objective optimisation of measures to improve the transit system, hardly any research efforts have incorporated the simultaneous optimisation of interventions to discourage car usage. In this presentation, we study this gap in the current literature. In doing so, we demonstrate the potential of combining the transit and car network design when trying to shift towards a more sustainable mobility system.

3 - Sustainability in Island Waste Transportation

Javier Maturana-Ross, Lorena Bearzotti, Franco Basso

Island waste transportation involves moving waste material generated within these remote regions, often characterized by limited infrastructure and unique geographic constraints. These conditions frequently create substantial barriers to sustainable waste management, resulting in inefficient collection and disposal methods, elevated transportation expenses, and detrimental environmental impacts. This research is motivated by previous studies on island transportation planning, which focused on optimizing transportation routes in these regions. Despite existing literature on island waste transportation, there is a notable gap in addressing the sustainability aspects of waste transportation. This study aims to contribute to the literature by incorporating sustainability criteria into the transportation planning model for waste collection in island and remote regions, and also other issues that might arise in waste transportation, such as community engagement, ecological preservation, and public health safety, among others.

4 - The International Logistics Performance Index as A Useful Predictor of Trade openness: A Classification and Regression Tree (CART) Analysis

Danny Cho, Tomson Ogowang

An important attribute of globalization is the escalation of the movement of goods across international borders, heightening the need for trade facilitation. In 2007, the World Bank released the maiden version of the Logistics Performance Index (LPI) as a numerical yardstick for gauging progress towards trade facilitation. The LPI is an equally weighted six-component composite index that lies between 1 (the worst-case scenario) and 5 (the best-case scenario). The LPI provides valuable information to many stakeholders around the world, including supply chain and logistics professionals, academics, and trade agencies, among others. The purpose of this paper is to examine the ability of the individual components of the LPI to predict trade openness (where trade openness is defined as the sum of exports and imports, expressed as a percentage of GDP). The empirical analysis of the latest LPI data is conducted using Classification and Regression Trees (CART), which does not only have the advantage of capturing potentially complex relationship between the individual LPI components and trade but also lead to the identification of the most important components based on the trimming algorithm. Our empirical results indicate a strong potential of CART in enhancing the usefulness of the LPI.

1 - Joint schedule and volume optimization at scale

Marc Bataillou Almagro, Konstantinos Benidis, Martin Gross

The joint schedule and volume optimization aims at creating an optimal truck schedule with a corresponding volume plan that can satisfy the demand of the network in a speedy manner and with minimum cost. The speed of delivery is related to the path that a package follows

from an origin up to a final destination node, while the cost is proportional to the number of trucks that we schedule in order to move all the required packages. The problem has many operational and practical constraints that make it challenging. For example, all sites have inbound and outbound restrictions and capacity constraints, the packages are consolidated in intermediate nodes (sort centers) in various ways, there are driving bans that the schedule needs to comply with, etc. The problem is formulated as an MILP, to which we apply a set of techniques to reduce complexity such as smart pruning of decision variables and solving sequentially the problem to incrementally finer granularities. Experimental results on large-scale networks illustrate the effectiveness and scalability of our method.

2 - Capacitated Network Design for Multicommodity Flow problems with Sparse Commodities

Allan Sapucaia, Nikos Liakopoulos

Finding a timely and minimum cost truck schedule to transport packages closer to the customer through the Amazon Middle Mile Network is a big challenge. We breakdown it down into steps, where here we will focus in the combinatorial problem of deciding the equipment (truck and trailer) type, their departure time and the commodity demand mix carried, while the fulfilment paths and commodity demand are predetermined. We model the middle mile network as a time expanded graph, where nodes describe facilities, as well as their inbound and outbound, and arcs are either fixed and capacitated according to the availability of a shared resource, or schedulable connecting different facilities, with different options of trailer capacities and costs. Since a commodity will flow through a predetermined sequence of sites, each commodity traverses a very limited fraction of the network. We call this problem variation Capacitate Fixed-Charge Network Design for Multicommodity Flow Problem with fixed arcs and sparse commodities. We present a scalable integer linear-programming based matheuristic for the problem and show how many existing results from the broad network design literature can be adapted to the problem we are solving.

3 - Optimized demand-based charging networks for long-haul trucking in Europe

Jan-Hendrik Lange, Daniel Speth, Patrick Plotz

The transition from diesel vehicles to tailpipe emission free technology such as battery electric trucks (BETs) in surface transportation is crucial to meet the ambitious decarbonization goal set by the European Union. While the first models of electric heavy goods vehicles have become available, the charging infrastructure necessary to operate these vehicles is still largely absent. At the same time, current BET models exhibit limited range and increased refueling times, which creates a number of challenges in both the operational and strategic planning domain. We present work on mathematical models and algorithms to support decision making for the placement of BETs and corresponding charging infrastructure. Our efforts are directed towards internal strategic planning as well as collaborations with industry, academic partners and public policy. The goal of our external collaborations is to foster the coordination of charging infrastructure investments across multiple parties, which will help to accelerate the transition to carbon free transportation.

1 - Optimizing Bundling Choices in Online Food Delivery

Çağrı Doğuş İyican, Ahmet Çınar, Yahya Ertuğrul Geçkil, Muhammed Enes Oral, Batuhan Bayrakçı, Umut Toparlak

The digital revolution has brought about profound changes in the food service industry, particularly with the emergence of online food delivery. Our study aims to delve into the intricacies of order bundling to not only enhance courier satisfaction but also to maximize operational efficiency. Leveraging a combination of a Clarke and Wright heuristic and MIP model with a careful consideration of factors such as route length and operational constraints, we developed robust strategies geared towards improving bundled order ratios. A significant hurdle we encountered was the challenge posed by courier complaints regarding route structure between buyer locations. To effectively address this issue, we introduced a variety of angle constraint structures into our model. The outcome was striking - a substantial 7% increase in bundled orders was achieved without any compromise on route lengths, underscoring the pivotal role of prioritizing courier satisfaction in operational decision-making processes. In summary, our research provides invaluable insights into the optimization of online food delivery operations. By placing a premium on courier satisfaction and proactively tackling operational challenges, we present actionable recommendations for enhancing overall efficiency and service quality within the industry.

2 - Assessment of Sustainable Third-Party Reverse Logistics Providers Using Interval Rough DOBAS Approach

Nila B, Jagannath Roy

In the contemporary business landscape, reverse logistics (RL) activities play a pivotal role for companies aiming to achieve cost savings, improved customer service, and sustainability. Owing to resource constraints and a shortage of technology and expertise, manufacturing firms frequently form partnerships with specialized RL service providers. Yet, assessing the optimal third-party reverse logistics providers (3PRLPs) poses a challenging and uncertain multi-criteria decision-making problem. This paper introduces an innovative framework integrating interval rough numbers with the Dombi Bonferroni Weighted Assessment (DOBAS) model. The objective is to offer systematic decision support for organizations in selecting the most suitable partner. The proposed methodology was verified and implemented in evaluating 3PRLPs providers for an Indian food manufacturing company (FMC). Fourteen criteria from sustainable aspects - environmental, economic, social, and risk factors- were used to evaluate and rank six 3PRLPs. The evaluation results provided valuable insights into the strengths and weaknesses of each provider, allowing the FMC to make an informed decision on which 3PRLP to partner with for their needs. The outcomes demonstrated that the proposed approach is a valuable tool for supporting decision-making, and it is not only applicable to the case discussed in this work but also to other situations of a similar nature.

3 - Optimizing Material Logistics in Dynamic Production Settings

Masood Fathi, Amir Nourmohammadi

In today's competitive market, characterized by demanding levels of product customization and variant production, the significance of a reliable and agile logistics system cannot be overstated in promptly meeting material demands at production lines. However, the uncertainties inherent in the production process and unplanned changes to the production plan pose significant challenges to achieving optimal in-plant material delivery for logistics planners. This study proposes a solution comprising a mathematical optimization model and a simulation-based optimization approach to assist material logistics planners in manufacturing companies in swiftly adjusting material delivery to accommodate changes in the production plan. The effectiveness of the proposed solution is validated through the resolution of a real case problem, demonstrating its practical applicability and benefits in modern manufacturing environments.

4 - A Robust Time-dependent Green Location-Routing Problem With Time Windows

Saba Siadati, Virginie Lurkin, Mehrdad Mohammadi, Tom van Woensel

This study addresses the dynamic challenges of urban transportation in logistics caused by time-varying traffic congestion, introducing the Robust Time-Dependent Green Location-Routing Problem with Time

Windows (R-TDGLRP-TW). A key innovation is incorporating a time-dependent speed function, strategically capturing the nuanced dynamics of urban transportation. Additionally, the inherent uncertainty in travel speed (time), which significantly impacts the system's performance, is considered in a robust optimization context. The R-TDGLRP-TW optimizes hubs, vehicle routes, and delivery schedules, minimizing economic and environmental costs. To tackle this, we develop a mixed-integer linear programming model for R-TDGLRP-TW, incorporating the linearization of dynamic programming recursive equations proposed in the literature into a deterministic formulation. A metaheuristic solution algorithm is then used to solve large-scale instances efficiently within a reasonable computation time. Our focus on the dynamic aspects of urban transportation aims to efficiently provide practical insights, helping service providers navigate the complex trade-offs encountered in logistics planning.

OR in Accounting: Planning, Taxation, and Reporting

*Stream: OR in Financial and Management Accounting
Invited session*

Chair: Matthias Amen

1 - Defining reportable segments - a complex assignment problem in international accounting

Matthias Amen

IFRS 8 "Operating Segments" requires the grouping of operating segments into aggregated segments. A differentiated, aggregated presentation of assets and liabilities, income and expenses has to be reported separately for these reportable segments. A reportable segment should consist of one or more operating segments that are similar. Not all operating segments need to be aggregated into one reportable segment. The problem can therefore be characterised as a binary assignment similar to the Knapsack problem.

IFRS 8 defines sets of different requirements for the definition of reportable segments. The overall objective is up to the reporting company itself. To this end, we use a technical objective function that aims to minimise the dissimilarity inside reportable segments. By choosing different values for a weighting parameter in the formal objective function, we can generate solutions with a different number of reportable segments.

We formulate and solve the problem using AMPL and standard solvers. This also enables a discussion of IFRS 8 to improve future standard setting.

2 - Bandwidth planning for public authorities using the example of german municipalities

Christian Fritze

Public authorities are obliged to prepare annual budgets. The planning process regularly takes place in a two-way process between the administrative board and specialist departments and is predominantly based on a qualitative forecasting methodology and the updating of the previous year's plans. However, subsequent plan/actual comparisons regularly show that the actual values realized deviate significantly from the planned values in some cases. The uncertainty of developments in the next financial year appears to be too great for the predominantly applied qualitative methods for determining budget estimates to be sufficient to generate budgets that are stable in the sense of low deviations between planned and actual figures. This is taken as an opportunity to develop a quantitative planning methodology with the aid of Monte Carlo simulation in order to take better account of distribution and event risks. A multi-stage procedure is presented, which takes into account the special features of public administration operations and includes suggestions for practical implementation.

3 - Tax incentives to facilitate sustainable investments

Carolin Famulla

With the so-called EU-taxonomy regulation in 2020, the European Union established a uniform classification system to determine environmentally sustainable economic activities. According to the EU regulation, economic activities are environmentally sustainable if they contribute substantially to the achievement of certain environmental objectives, e.g. climate change mitigation or pollution prevention and control. Insofar as they do not explicitly contribute to the environmental objectives, economic activities should not significantly harm the environmental objectives. The EU regulation includes a range of measures to achieve the defined environmental objectives. Incentives should be provided to invest in sustainable and climate friendly economic activities. In this context, the question arises which tax incentives exist to facilitate sustainable investments and how these incentives affect the investment decision. I implemented different tax incentive measures, like levying an environmental tax or tax exemptions for sustainable investments, and investigated their effect on the investment decision made on basis of the net present value criterion. This is compared with the case that the decision is only made on basis of the tax burden.

4 - The Government Contracting Supply Chain and Financial Reporting

Tracie Frost

This study explores the impact of government contractors' supply chain characteristics on contractors' financial reporting decisions related to risk, cost, and compliance. Supply chain contracts are economically important and subject to substantial risks, as shown by reporting of supply chain risks in firms' Item 1A disclosures; however the exact influence of supply chain risks on financial reporting outcomes remains unclear due to the lack of publicly available contract details for commercial supply chains. To overcome this issue, I use detailed data from US government contracts. Government contractors an institutionally interesting setting for studying supply chain contract characteristics because they operate within complex bureaucratic frameworks and accounting guidelines, which require robust financial operations to remain in compliance with regulations. Government contracts also account for approximately 13% of public firms' major customers. Given the importance of government contracts and the detailed contract data that is available, this study investigates how supply chain contract characteristics influence financial reporting decisions. Specifically, leveraging data from the Federal Procurement Data System, I analyse the impact of these characteristics on financial reporting outcomes, including how managers identify, assess, and mitigate risks associated with government contracts; track and control contract costs; and manage audit risk and control weaknesses.

Job shop scheduling

Stream: Project Management and Scheduling
Invited session

Chair: [Andrea Corsini](#)

1 - Periodic and Real-Time Dispatching Rule Selection for the Dynamic Job Shop Scheduling Problem

Nuno Marques, Gonçalo Figueira, Luis Guimarães

Aggressive competition and wider production mixes are profoundly impacting manufacturing settings, which, in turn, have become more technological, flexible and dynamic. With growing uncertainty in the shop floor, dynamic scheduling emerged as a relevant topic to explore. In highly dynamic environments, dispatching rules (DRs) became a popular solution method for scheduling problems due to their reactive nature, ease of implementation and interpretability. However, DRs do not cope well with varying conditions in two main dimensions: shop

load and job urgency. Therefore, researchers have proposed machine-learning-based systems that select DRs as conditions change over time. Two main approaches emerged in the literature: the periodic rule selection (PRS) and the real-time rule selection (RTRS). The goals of this work are twofold. First, propose PRS and RTRS systems that can outperform state-of-the-art DRs by relying on effective state and action sets. Secondly, contrast PRS and RTRS in the same dynamic job shop instances for stationary and non-stationary conditions, filling a gap in the literature. Results show that the best rule selection system reduces tardiness, on average, 14.8% in stationary instances, and 3.5% in non-stationary instances. Even in the hardest instances, the system comes within 1% of the best DR. Moreover, PRS reveals to be the most effective approach for stationary instances. In non-stationary conditions, RTRS was better.

2 - Evaluation of VaR and CVaR for the Makespan in Interval Valued Blocking Job Shops

Marcella Samà, Marco Pranzo, Carlo Meloni

We take into account the blocking job shop scheduling problem (BJSS) where processing, release and sequence-dependent setup times have uncertain interval durations. Scheduling problems which take uncertainties into account are computationally complex and the literature on stochastic and uncertain scheduling is relatively limited compared to the that on deterministic scheduling. As such, analysts often use deterministic models that incorporate simplified representations of the most relevant stochastic aspects in order to determine or select the schedule to implement. We propose a method for the evaluation of the risk that the makespan of deterministically computed solutions worsens under the worst-case realizations of the uncertainty. An interval-valued network approach is proposed to model the feasible solutions characterized by uncertain values on the given constraints' durations. The study assumes the Value-at-Risk and the Conditional Value-at-Risk as measures, and addresses both modeling and computational issues. The impact of different sources of uncertainty on the overall performance of the proposed approach is analyzed. The results of the experimental campaign show that the method, for both the computational time and the quality of the evaluations, has broad applicability and can support the decision-makers for taking into account their risk sensibility.

3 - A generic and efficient insertion-based heuristic for shop scheduling problems

Karim Tamssaouet

Due to the complexity of shop scheduling problems, research over the past three decades has mainly focused on the development of improvement heuristics, while construction heuristics are often neglected. Sometimes low-performing construction heuristics are deliberately used to demonstrate the robustness of the improvement heuristics. Yet, effective and efficient construction heuristics play a crucial role in solving large practical problems. Most of the constructive heuristics in the literature are based on priority rules. Another type of heuristic is based on successive insertions of operations in partial schedules. Only a few, powerful insertion-based heuristics are known in the literature, especially for the flow shop and job shop scheduling with makespan minimization. However, in addition to being tailored to a specific problem, compared to priority-based heuristics, these methods suffer from a high computational cost if not carefully designed. In this work, we show that it is possible to have a generic insertion-based construction heuristic that can solve any shop scheduling problem with regular objective function and for which an acyclic directed graph with nonnegative weights can represent a solution. The efficiency is achieved through novel procedures quickly evaluating the feasibility and quality of the insertion moves. Results on the flexible job and flow shop instances and their extensions (e.g., multiple modes and nonlinear routes) will be presented.

4 - Self-Labeling the Job Shop Scheduling Problem

Andrea Corsini, Mauro Dell'Amico

The Job Shop Problem (JSP) involves scheduling sequences of operations (jobs) on machines by minimizing the makespan [1]. Our novel approach tackles the JSP as a sequence of decisions, nicely represented by a branch-decision tree. At each decision node, we explore all the job selections for scheduling the next operation. We use an encoder-decoder architecture [2], where the Graph encoder creates embeddings

for operations from the disjunctive graph of JSP instances, and the decoder generates solutions by producing at each decision node a probability of picking each job from these embeddings. Given the high cost and expertise needed for applying Supervised and Reinforcement Learning, we propose a simpler Self-Labeling training strategy, which constructs multiple solutions and uses the best one as a self-generated label to refine the model. Our model outperforms Constructive Heuristics [1] and Reinforcement Learning approaches [3], with up to 20% reduction in optimality gaps, and also surpasses a disjunctive Mathematical Programming model on benchmark instances.

Retail Cooperation and Competition

Stream: Retail Operations
Invited session

Chair: Mehmet Sencer Zengin

1 - Pricing and procurement policies of two substitutable products under supply disruption risk

Mehmet Sencer Zengin, Özgen Karaer, İsmail Serdar Bakal

We study a supply chain that is composed of a manufacturer and a retailer. The retailer sells two vertically differentiated and substitutable products to the market and the products are supplied by the manufacturer. The lower-quality product has a stable supply, and thus, its wholesale and retail prices are assumed to be exogenous. The innovative (i.e., "high-quality") product's price is yet to be determined and its procurement/production is prone to supply disruption risk. We explore the optimal procurement quantities of both products and pricing decisions of the higher-quality product. As for the sequence of events, first, the manufacturer decides the wholesale price of the innovative product. Then, after observing this price, the retailer determines the order quantities of both products. Afterward, the innovative product is supplied or not with a certain probability. Finally, the retailer determines the retail price of the innovative product if no disruption and customers make purchase decisions.

We find that the market potential of the lower-quality product, which is determined by the quality perception and the retail price of that product, plays a crucial role in the optimal policies. When this potential is low, the innovative product is more inclined to be abandoned as its quality gets closer to the lower-quality one. Also, a precautionary stock of the lower-quality product should be kept to make up for a potential disruption of the innovative product.

2 - When should fresh-food suppliers embrace near-expired food commercialization?

Zhengwei Lyu

Despite widespread discussion that near-expired food commercialization (NFC) may assist fresh-food suppliers to recover value from unsold inventory and enhance revenues, most suppliers remain skeptical about NFC, hesitant to abandon the potential of and concerned about eroding the higher-margins of fresh food sales. We develop in this paper a game-theoretic model to investigate the optimal strategy and optimal price-setting timing for the supplier that decides whether and how to commercialize its near-expired food. We find that increasing fresh food production shifts the supplier from non-commercialization to partial and ultimately full NFC. Under full NFC, the supplier with high bargaining power and high consumers' willingness to pay may benefit from adopting clearance-priority pricing, which prioritizes setting of the retail price of the near-expired food. Conversely, the supplier with

limited bargaining power and low consumers' willingness to pay can gain an advantage by adopting fresh-priority pricing, which entails setting the retail price of the fresh food first. Under partial NFC, the supplier generally profits from clearance-priority pricing. However, given high disposal costs, even the seemingly strong supplier may choose fresh-priority pricing to avoid potentially significant losses from negotiation failure. We further analyze extended models to confirm the robustness of our findings. Our study not only contributes to the literature but also guides practice.

3 - Mismatch Risk, Alliance Stability and Production Efficiency in a Coproduct Supply Chain

Yangyang Peng, Xin Wang, Zhengfeng Liu, Mingyuan Zhu

Products (e.g., cattle and pig) can be processed into several types of products (parts) targeting different segments of customers, which belong to the so called coproducts. Mismatch risk, alliance stability and production efficiency are three significant issues in such coproduct logistics and supply chain. First, we use the unbalanced ratio to reflect the degree of mismatch between supply and demand among different parts of the coproduct and study how the tradeoff between the bargaining power and the mismatch cost, by different mismatch risk allocations, influences the optimal decisions and the performances of the two parties as well as the whole logistics and supply chain. Then, we investigate how the coproduct alliances are formed considering tradeoff between processing cost and mismatch ratio among heterogeneous retailers. We establish a general collaborative game model and study the existence of the core of the grand coalition and extend the model to the multi-retailer settings, and the general distribution with the cost-least consideration. Finally, in view of the product line design of the coproduct supply chain, considering the uncertainty of the market size, the size and length of the product line of the coproduct supply chain are analyzed and we expand to multiple products and general distribution of customer types and market size. We endeavor to provide some new insights into coproduct logistics and supply chain management at the theoretical level.

4 - Information Sharing and Manufacturer Rebate Competition

Albert Ha

We investigate the incentive for a retailer to share private demand information with two rebate-offering manufacturers who sell substitutable products through the retailer. We characterize how the retailer's information sharing decision depends on key factors such as the proportion of rebate-sensitive consumers and competition intensity. Without side payment, the retailer will not share information with a monopolistic manufacturer, but he may do so with none, one or both of the manufacturers when there is competition. With side payment, the retailer always prefers to sell information concurrently instead of sequentially to the manufacturers.

Machine Learning and Optimization in Ports II

Stream: OR in Port Operations
Invited session

Chair: Frederik Schulte

1 - Machine Learning Approaches for improved ETA Predictions and Turnaround Times of Inland Vessels at Sea Ports

Peter Wenzel, Zhong Chu, Frederik Schulte

Predicting accurate Estimated Times of Arrival (ETA) for Inland Waterway Transportation (IWT) remains a challenge to coordinate port operations and reduce waiting. Captains report ETAs on inland vessels based on the remaining distance to the destination and the captain's experience. A comprehensive literature review highlights the current methods for ocean-going vessel trajectory-based ETA prediction, ocean-going feature engineering for direct prediction, and predictions of ETA times in IWT. The experiments use historical position data (AIS) reported by vessels heading to the port of Rotterdam, as well as dimensions of the vessels, weather conditions, and water levels. Several machine learning methods using Neural Networks, Gradient-Boosted Decision Trees, and Light Gradient-Boosting Machines are proposed to predict ETA at the Port of Rotterdam. Predictions are then compared with the captain's ETA and the Actual Arrival Times (ATA). This paper shows that the predictions of ETA times are 98% more accurate than the captain's ETAs. Compared to the ATA, our predictions are 99% accurate. These learning-based approaches can be further used in IWT research to create learning-informed optimization and simulation to reduce vessel turnaround times. In practice, this improved accuracy of arrival time prediction will enhance the reliability of IWT and enable the port to develop an accurate terminal visit schedule for the inland barges.

2 - Explainable Decision-Making for Stochastic and Dynamic RoRo Ship Operations

Arne Heinold, Teresa Marquardt, Frank Meisel, Catherine Cleophas

Our research addresses the loading and unloading problem for Roll-on/Roll-off (RoRo) ships, a critical aspect of maritime logistics. Embracing the complexity of real-world uncertainties, this study explores the impact of varying levels of data availability, facilitated by new telecommunications technologies. Realistic real-world problems face the challenges of stochastic and dynamic aspects, such as uncertainties regarding the type of cargo or process times.

To solve this high-dimensional decision problem, we model it as a sequential decision process and use a hierarchical solution method similar to classification and regression trees (CART). The proposed solution approach yields solutions of short turn-around times but also provides explainability in decision-making. We test our approach against myopic decision policies using real-world scenarios from the Port of Kiel. Subsequently, we apply our methodology to illustrate the influence of different data availability levels, providing specific recommendations regarding the benefits of additional data.

Risk Management in Private and Public Finance

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management
Invited session

Chair: *Loretta Mastroeni*

1 - Security Breach Probability Models

Maurizio Naldi

Cybersecurity breach probability functions describe how cybersecurity investments impact the actual vulnerability to cyberattacks through the probability of the attack's success. They essentially use mathematical models to make cyber-risk management choices. This talk provides an overview of the breach probability models that appear in the literature. For each of them, the form of the mathematical functions and their properties are described. The models exhibit a wide variety of functional relationships between breach probability and investments, including linear, concave, convex, and a mixture of the latter two. Each

model describes a parametric family, with some models having a single parameter and others having two. A sensitivity analysis completes the overview to identify the impact of the model parameters: the estimation of the parameters which have a larger influence on the breach probability is more critical and deserves greater attention.

2 - LHP approximation for green-loan credit portfolios under skewed and heavy-tails returns

Alessandro Ramponi

In recent years, efforts to address climate change and promote the creation of an environmentally sustainable economy have intensified. This commitment has spurred the emergence of financial instruments designed to support activities commonly referred to as "green". Financial institutions, as well as non-financial corporations or local governments, engage in lending activities to fund challenging low-carbon transition objectives. This includes financing rooftop solar power, wind farms, environmentally friendly farming practices, water conservation, the leasing of hybrid and electric vehicles, and initiatives aimed at enhancing the energy efficiency of industrial, commercial and residential properties. One prevalent approach to model portfolio credit risk involves employing the LHP (Large Homogeneous Portfolio) approximation within the one-factor Merton-type framework, commonly referred to as the ASRF (Asymptotic Single Risk Factor) model. In this work we consider the classical Vasicek Gaussian model under more general distributional assumptions for the systematic risk factors. We specifically examine how the quantiles of the loss portfolio are affected by mixing distributions characterized by skewed and heavy-tail properties. This analysis is conducted in the context of loans, some of which are designated as "green", indicating their allocation towards financing environmentally sustainable assets.

3 - Risk management issues in current energy context

Ivan De Crescenzo

The current macroeconomic context of high interest rates and economic slowdown, both ignited by the gas crisis following the pandemic outbreak, is profoundly impacting the energy sector as well as others. Over the last year, renewables, most likely favoured by a reduced overall demand of power across the continent, have taken over a large share of the market, fostering decarbonization. Gas storage at maximum capacity, almost complete fuel-switch out of coal and decreasing price of carbon allowances seem not to imply profitable margins, with Clean Spark Spread and Clean Dark Spread both looking gloomy. Hence, by contrast, this arrangement is shaping up in nothing but the next trap for utilities. Particularly, carbon allowances experienced a drastic bearish movement far from being forecast. Over-hedging must be deemed as a possible common scenario many operators are currently navigating. Revenues reductions and variation margins are a threatening combination in this context of lack of liquidity. Whereas volatility and skyrocketing prices were yesterday's enemies, stagnation and industrial crisis appear to be the new challenges to tackle in power generation market.

4 - Systemic resilience of networked commodities

Roy Cerqueti

This paper aims at providing insights on the ability of systems of commodities to absorb external microscopic shocks. Such ability is labelled as systemic resilience. Commodities are suitably evaluated along with their interconnections, on the basis of the similarities of their financial performances. The resilience is measured through the comparison of the shocked networks with the original unshocked ones. The employed device is the clustering coefficient, which is a nodal centrality measure associated with the community structure of the network. The proposed methodology is empirically tested over a large set of commodities of different nature.

Wednesday, 10:30-12:00 - Room: S16 (building: 101)

Vehicle Routing Problems With Time Windows

Stream: VeRoLog - Vehicle Routing and Logistics
Invited session

Chair: [Pedro Munari](#)

1 - Territory Design Strategy for the Multiperiod Vehicle Routing Problem With Simultaneous Pickup and Delivery and Time Windows

Matías Cortés, Hernán Lespay, Carlos Obreque

The present study proposes a Territory Design Strategy for the Multiperiod Vehicle Routing Problem with Simultaneous Pickup and Delivery and Time Windows (TD-MPVRPSPDTW). This problem deals with the design of compact and contiguous territories to simultaneously collect and deliver orders from a warehouse to customers who have time windows requirements in a multi-period approach. This problem is motivated by the circularity of the supply chain because it helps to integrate the delivery and collection of products. Besides, the proposed territory design strategy lets generate consistent routing plans due to each driver being assigned to one territory. We proposed a mixed-integer linear programming model (MILP) for the problem, which is solved using a metaheuristic algorithm. We evaluate the performance of the proposed algorithm through benchmark instances.

2 - A Framework for Cluster-Based Heuristics for Vehicle Routing With Time Windows

Xinyi Ye, Dimitrios Letsios, Haoxiang Wang

We develop a novel framework for designing cluster-based heuristics to the Vehicle Routing Problem with Time Windows (VRPTW). Similarly to state-of-the-art cluster-based VRPTW approaches, our framework consists of a clustering and a routing phase. However, we also incorporate an intermediate pre-routing phase that allows using any existing VRPTW solution method (e.g. exact or metaheuristic) in the routing phase and scaling the method's performance. In this way, we can achieve different desired trade-offs between solution quality and running time efficiency. Further, our framework consists of configurable components in the clustering phase - namely, the number of clusters, clustering objective, and cluster feasibility - that can be customized to enhance the performance of obtained cluster-based VRPTW heuristics. Also, we embed an approach based on time discretization and incompatibility constraints in the clustering phase to ensure that time windows are respected. We computationally validate the effectiveness of our framework and its components using the Solomon benchmarks.

3 - Flowty's Resource Constrained Shortest Path Algorithm

Bjørn Petersen, Simon Spoorendonk

Flowty is a network optimization solver that exploits the network structure in a column generation algorithm. This talk is about the resource constrained shortest path (RCSPP) algorithm at the core of this algorithm.

The RCSPP algorithm is a bidirectional labeling algorithm parallelized on a bucket level, that is pulling (as opposed to pushing) labels into buckets. The size of the buckets is small enough to avoid cycles within the bucket.

Pulling into buckets is done in parallel for independent buckets. The dependency graph between buckets is handled implicitly, and the bidirectional midpoint/stopping criteria is dynamic, meaning that buckets are extended until the opposite direction is encountered.

As is always the case for pull-based labeling algorithms; carefully choosing the order of which labels are created, it is possible to guarantee that only labels not dominated are ever stored. This not only limits the memory footprint, it also allows labels to be stored as immutable

'object of arrays' (as opposed to 'array of objects') thereby enabling the use of vectorized instructions for dominance checks and thus exploiting a second level of parallelization.

The Vehicle Routing Problem with Time Windows (VRPTW) is used as an illustrative case.

4 - The Vehicle Routing Problem With Remote Drivers

Pedro Munari, Nils Boysen

Remote driving is a type of teleoperation that allows a human operator to control a vehicle without direct physical access, typically through wireless communication technologies. Recent advances in 5G wireless cellular networks, sensor technology, high-quality cameras, and machine learning have made remote vehicle operation more feasible and successful for a wider range of applications, both on public roads and inside facilities such as warehouses and factories. The main advantage is that remote drivers do not have to be idle during service operations at customers. Instead, they can switch to other vehicles, which opens up the possibility of operating a fleet more efficiently. In this talk, we introduce the Vehicle Routing Problem with Time Windows and Remote Drivers (VRPTWRD), which extends the traditional vehicle routing problem to include the specificities of remote driving. We model different versions of the VRPTWRD as mixed-integer programming problems, and use Benders decomposition to derive effective branch-and-Benders-cut approaches. Our results indicate that remote driving can effectively reduce the workforce needed to operate a fleet of vehicles.

1 - Disaster Resilient Cities: An OR Approach to Disaster Management

Bahar Yetis Kara

There have been decades of research in the field of humanitarian logistics, and academics in the field of logistics are becoming more and more interested in it. That being said, we still acquire insight and identify new problems with each disaster. We have also observed various humanitarian logistics applications during COVID-19, e.g. for PCR test sites and vaccination centers. Unfortunately, the recent earthquake in Turkey has led us to re-evaluate the response cycle of disaster management. Close inspection reveals that this response phase actually leads to a variety of new applications of distribution logistics problems. We have conducted many meetings and workshops with municipalities that were very active during the response of the Maraş Earthquakes. Many municipalities aim to have "earthquake-resistant cities" with correct action plans and being ready for potential disasters. Based on our discussions with these municipalities, we have developed an "ideal action plan". We also investigated the potential decision problems and linked these problems with OR literature.

Portfolio Optimization: Models and Methods

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: Roy Cerqueti

1 - Optimal portfolios' weights and rank-size shapes

Alessio Di Paolo, Roy Cerqueti, Francesco Cesarone, Valerio Ficcadenti

In this work, we study the relationship between the mean-variance-based portfolio optimization algorithms' inputs parameters μ and Σ and the rank-size function's law's estimated parameters from the best fit on the resulting sorted weights distribution. The objective is to explore the way weights describe a unified framework once they are ranked according to their sizes and, at the same time, the implications on the optimal allocation outcomes. Indeed, characterizing portfolio weights through rank-size curve parameters allows us to understand how portfolio risk and return vary as these parameters change.

2 - Tracking-based green portfolio optimization

Diana Barro, Marco Corazza, Gianni Filograsso

In this contribution, we discuss how to handle financial and sustainable investment goals, focusing on greenness and ESG features. Among thematic investments, green and energy-related ones have emerged, capturing investors' attention. This contribution introduces a novel ESG-focused tracking error model to provide ESG-tailored-made allocations. We consider two reference benchmarks, accounting for a financial target and an ESG one, respectively. The objective function

results in a convex linear combination of the two goals where the combining parameter accounts for the investor's financial and ESG preferences. A symmetric tracking error measure is proposed to replicate the financial benchmark passively, while an asymmetric measure is used to track and possibly outperform the thematic ESG benchmark. Identifying the benchmarks for the two components represents a crucial step and, jointly with the choice of the combining parameter, accounts for the portfolio's overall risk-return and ESG profiles. In the model, the sustainability feature is handled not only with the presence of the ESG benchmark but also with the introduction of dedicated constraints. An application to the EUROSTOXX 600 equity market is presented and discussed for different choices of the combining parameter, representing different sustainability preferences and risk-return profiles.

3 - Managing ESG Ratings Disagreement in Sustainable Portfolio Selection

Manuel Luis Martino

The inclusion of sustainable goals in the portfolio selection process may have an actual impact on financial portfolio performance. Environmental, Social, and Governance (ESG) indices provided by the rating agencies are generally considered good proxies for the performance in sustainability of an investment, as well as, appropriate measures for Socially Responsible Investments in the market. In this framework, the lack of alignment between ratings provided by different agencies is a crucial issue that inevitably undermines the robustness and reliability of these measures. Indeed, the ESG rating disagreement may produce conflicting information, implying a difficulty for the investor in the portfolio ESG evaluation. This may cause underestimation or overestimation of the market opportunities for a sustainable investment. In this paper, we deal with a multicriteria portfolio selection problem taking into account risk, return, and ESG criteria. We present a new approach to manage the ESG ratings disagreement between different agencies. We propose a nonlinear optimization model for our three-criteria portfolio selection problem. We show that it can be reformulated as an equivalent convex quadratic program by exploiting the k-sum optimization strategy. An extensive empirical analysis of the performance of this model is provided on real-world financial data sets.

4 - Stabilizing financial networks via mergers and acquisitions

Markku Kallio, Aien Khabazian

A bi-level model is proposed to explore efficient policies for supporting negotiations on financial crisis resolution. In a principal-agent framework, this model minimizes a welfare loss function of a central authority (social planner, SP) by simultaneous choice of subsidy levels and potential pairs of banks to merge. The SP's choice of mergers needs to be incentive compatible with autonomous choices of banks and the evaluation of the financial network must obey standard accounting principles. Incentive compatibility is enforced by two options of conditions based on stable matching or competitive bidding. For the evaluation of a financial network, we employ an extended Eisenberg-Noe clearing payment equilibrium by considering bankruptcy costs and seniority levels of liabilities. Additionally, liabilities are not cleared among solvent banks and corporate bonds may be used for clearing payments. The bi-level model states conditions for the clearing equilibrium. For demonstration we use major European banks and a scenario which is linked to the adverse economic scenario used in 2016 EU-wide stress testing.

Applications of Mixed-Integer and Nonconvex Optimization 1

Stream: MINLP

Invited session

Chair: Alireza Olama

1 - Bilinear Branch and Check Algorithm

Ponpot Jartnillaphand, Hoa Bui

In this presentation, we introduce the bilinear branch and check algorithm, an exact method for solving nonlinear optimization problems. This approach extends the classical branch and check algorithm by integrating bilinear constraints into the search process. The enhancement of the bilinear constraint refines the problem formulation, expediting the convergence of the search. The algorithm decomposes problems into manageable subproblems, utilizing the branch and cuts to assess feasibility and generate feasibility cuts (no-good cuts), while also enhancing master problem solutions. A key innovation lies in the algorithm's methodology for improving master problem solutions and constructing high-quality no-good cuts among decision variables. This allows for further decomposition of the master problem, enhancing its effectiveness. Our numerical results demonstrate promising outcomes and exhibit greater efficiency compared to standard branch and cut methods like IBM CPLEX and the classical branch and check.

2 - Distributed Interpretable Machine Learning on GPUs

Alireza Olama, Andreas Lundell, Jan Kronqvist

The research introduces the Bi-linear consensus Alternating Direction Method of Multipliers (Bi-cADMM) to address large-scale regularized Sparse Machine Learning (SML) problems over a network of computational nodes. These problems involve minimizing local convex loss functions over a global decision vector with an explicit ℓ_0 norm constraint to ensure sparsity. This approach generalizes various sparse regression and classification models, including sparse linear and logistic regression, sparse softmax regression, and sparse support vector machines. Bi-cADMM reformulates the original non-convex SML problem using bi-linear consensus and employs a hierarchical decomposition strategy. This strategy splits the problem into smaller, parallel-computable sub-problems through a two-phase approach: initial sample decomposition and distribution of local datasets across nodes, followed by a delayed feature decomposition on GPUs available to each node. GPUs handle data-intensive computations, while CPUs manage less demanding tasks. The algorithm is implemented in an open-source Python package called Parallel Sparse Fitting Toolbox (PsFIT). Computational experiments validate the efficiency and scalability of Bi-cADMM through numerical benchmarks on various SML problems with distributed datasets.

3 - Multiscale optimal mass transport

Martin Ryner

We present a simple to implement multiscale entropy regularized Optimal mass transport solver using wavelet decomposition. The framework iteratively gives the user approximations to the optimal solution at a coarse to fine resolution and is particularly of interest for large scale problems with continuous costs and marginals. We discuss convergence, computational cost and show some examples.

1 - Understanding the structure and dynamics of the global vaccine product trade network.

Rui Zheng, Luis Ospina-Forero, Yuwang Chen

The most economical measure for tackling public health emergencies is mass immunization. During crises, policymakers heavily rely on global human vaccine product trade as it profoundly shapes the development of additional intervention measures. Drawing on global human vaccine product trade data from 2019 to 2022, this study employs social network analysis methods to explore the structure of the global human vaccine product trade network from various network statistical features such as community structure and evolution. In addition, through a comparative examination of global monthly trade networks for human vaccines, this study reveals the evolving structural dynamics amidst the global public health crisis (COVID-19), offering insights into how it affects national intervention strategies and vaccine market stability during pandemics. Overall, the global human vaccine product trade network has experienced an increase in its scale with an extended multipolar structure. Additionally, the alterations in network structure revealed by trade volume and frequency can also demonstrate competitive dynamics and behaviors between countries, and highlight the shifts in vaccine strategies among countries during public health emergencies. High-income countries with rapid vaccine rollout and introduction (such as the United States) exhibit stronger resilience by actively adopting comprehensive intervention measures.

2 - From docket to data: unpacking judicial congestion using process- and queue-mining

Shany Azaria

The court system, pivotal for social justice, is overflowed by congestion affecting social welfare, economic development, and access to justice. Despite its significance and operational complexity, being characterized by constrained resources, increasing demand, long in-process waiting time, impatient customers, and LOS measured in years, empirical research on court operations remains limited. This scarcity is largely attributable to challenges in accessing reliable and comprehensive data. This study employs NLP and AI tools to transform two decades of US Federal District Court case dockets into a detailed event log, leveraging process- and queue-mining to explore judicial congestion. By scraping, labeling and analyzing millions of docket entries through operations management lenses, we are able to observe the case flow in the system and assess congestion impacts on case processing. Our findings illuminate the judicial workflow, offering insights for reducing congestion and enhancing system efficiency. This pioneering approach underscores the potential of data-driven analysis in court systems operations.

3 - Integrating machine learning in measuring multidimensional energy poverty: new insights from a survey analysis in Europe

Rahil Dejkam, Reinhard Madlener

Energy poverty, a multidimensional socio-economic challenge, significantly affects the welfare of many people across Europe. This paper aims to alleviate energy poverty by exploring sustainable energy practices and policy interventions, using household survey data from Portugal and Denmark. A Multidimensional energy poverty index (MEPI) is developed to assess energy poverty through different dimensions such as heating and cooling comfort, financial strain, access to energy-efficient appliances, and overall health and well-being. In a next step, for selecting features, machine learning techniques are employed including recursive feature elimination and random forest analysis. These methods help to reduce the number of irrelevant and mutually correlated predictors. Subsequently, a logistic regression model is used to predict energy-poor households based on selected socio-economic, and policy-related factors. The logistic regression results indicate that sustainable energy-saving behaviors and supportive government policies can mitigate energy poverty. Furthermore, for analyzing the impact of determined features the Shapley additive explanations (SHAP) method is being utilized. Finally, the main findings are evaluated further via scenario simulation analysis. The result shows that fully adopting waste-compositing and energy-efficient microwave ovens can decrease the proportion of energy-poor households by 93% and 79%, respectively.

4 - An artificial neural networks model to production rate estimation of short and medium sized serial production lines

Mehmet Ulaş Koyuncuođlu

Accurate analysis of production lines is of critical importance at strategic and tactical level for the sustainable economy of companies. Production rate, which is defined as the amount of production per unit time. The processing times, failure times and repair times (reliability parameters) of the machines and the number of buffers used between machines to reduce idle times greatly affect the production rate, which is one of the main performance indicators. Unreliable lines, where machines are subject to random failures, and balanced production lines, where the processing time of all machines is equal or expressed by independent identically distributed random variables. Exact analytical methods, approximate analytical methods and simulation are widely used for production rate calculation. Estimation of the production rates with artificial intelligence-based methods are very limited in terms of production line configuration and belong to recent years. In this study, an artificial neural network model is proposed to accurately and quickly estimate the production rate of small and medium-sized serial production lines with all machines in the line balanced, unreliable, finite buffer size. Parameter tuning is performed for the proposed artificial neural network model and additional tests are conducted to increase the prediction efficiency of the model. The results obtained encourage the proposed model to be applied to large size lines.

Behavior in supply chain collaboration

Stream: Behavioural OR

Invited session

Chair: Yingshuai Zhao

Chair: Jose Benedicto Duhaylongsod

1 - Learning organization and product quality performance: A moderated mediation model

Jose Benedicto Duhaylongsod, Sheldon Carvalho, Irene De Pater

This paper examines how a learning organization affects product quality performance from a behavioral operations perspective. Drawing on social information processing theory and social capital theory, we develop a theoretical model proposing (1) how a learning organization positively affects product quality performance through internal integration and (2) how employees' supply chain management competencies amplify this relationship. We test our model using a longitudinal survey with three waves of data collection from employees in leadership positions in operations, manufacturing, and production functions located in the United Kingdom. Our findings support the proposed relationships. These results highlight the importance of aligning organizational processes and employees' competency development in driving cooperative work across functions and enhancing product quality performance.

2 - Humans respond to machines' response times in human-machine interaction

Zhi Zhu, Yingshuai Zhao, Fadong Chen

The field of human-machine interaction is increasingly focusing on the anthropomorphism of computerized agents, especially their design to mimic human behavioral patterns. This research investigates a pivotal question: Do humans respond to human-like agents in the same way as they do to human counterparts in interactive scenarios? We explore this question using lab experiments within a supply chain bargaining context, where the supplier has private information about production

costs. The retailer proposed wholesale prices to the supplier, and decisions to accept or reject these offers were made by a computerized agent acting on behalf of the supplier. We find that individuals respond to the response time of agent partners similarly to how they respond to human partners. Compared to human-human bargaining, the retailer's profit is lower and the supplier's profit is higher in human-machine bargaining. These findings hold significant implications for the design of online bargaining tools in e-business, particularly in enhancing the use of human-like agents in commercial negotiations.

3 - Does audit backfire on corporate social responsibility? An experimental study on supplier's behaviours and motivations

Luyao Li, Xiaobo Zhao

We consider a setting of corporate social responsibility (CSR) that suppliers choose responsibility effort and hiding effort, given buyers' audit levels. Theoretical research indicates a potential "backfiring condition" where increased audits drive suppliers to prioritize hiding evidence of CSR violations over investing in social responsibility. To validate this prediction, we conduct a behavioural experiment with two treatments to examine suppliers' decisions in responsibility and hiding efforts under low and high audit levels. Different from the standard model's prediction of significantly higher responsibility efforts in the low-audit treatment compared to the high-audit treatment, experimental results show no significant difference. Additionally, actual hiding efforts by suppliers significantly exceed (fall below) the theoretical value in the low-audit (high-audit) treatment. We build a behavioural model consisting of probability weighting, mental accounting, and bounded rationality. Structural estimation of behavioural parameters shows that probability weighting leads suppliers to increase hiding efforts and reduce responsibility efforts. Conversely, mental accounting causes suppliers to overvalue the additional loss from CSR violations exposure, prompting higher responsibility efforts and lower hiding efforts. These findings highlight the necessity of comprehensively considering the decision biases in supply chain social responsibility management.

4 - Shining light and harnessing shadows: The dual role of authentication platforms in online luxury retailing

Baolong Liu, Yanlu Zhao

This study examines an emerging type of online authentication platform for luxury products retailing, which has not been fully investigated due to its novel business models and innovative characteristics. While regular online retailing business delivers products directly from the sellers to consumers, such platforms first provide authentication services and then fulfill the orders. On the one hand, authentication builds trust between sellers and consumers to encourage authentic-product-selling behavior and expand demand (shine light), it also helps consumers avoid counterfeits by reducing counterfeit-selling behavior (harness shadows). On the other hand, it is costly, time-consuming, and sometimes even misidentifies items. To understand whether this lengthy and expensive process benefits both sellers and consumers, we develop queueing models to characterize sellers-authenticator collaboration and its impacts on consumer welfare. The analysis reveals that a collaboration, which increases both the authenticator's and the sellers' profit, may hurt consumer welfare due to the authentication fee and waiting, especially at intermediate levels of honesty and market belief. The results are shown to be robust through extensive experiments. As a practical remedy, we recommend that authenticators implement seller management systems to increase the level of honesty, which benefits all stakeholders.

1 - The effect of multiple cues on the quality perception of crowdfunding products: A cue diagnosticity framework

Yao Zhang

This paper utilizes a cue diagnosticity framework to differentiate between high-scope cues (the founder's social capital and online comments) and low-scope cues (the number of pictures, sentences and videos), and empirically investigates how these two types of cues are diagnostic in the process of assessing the product quality. Based on the cue diagnosticity framework, under different high-scope cues, this paper puts forward hypotheses about the influence of low-scope cues on backers' quality perception of crowdfunding products. The findings show that regardless of the social capital and comments of founders, the number of pictures and videos in the introduction of reward-based crowdfunding will have a positive impact on the quality perception of crowdfunding products. When at least one of the founder's social capital or comments is good, the number of sentences will have a positive effect. However, when the founder's social capital and comments are poor, the number of sentences will have a negative impact on the quality perception of products. Furthermore, we replace the dependent variable and change the classification method of backer's social capital to ensure the robustness of the results. This paper enriches the research of reward-based crowdfunding, and provides important implications for founders to raise more funds from backers by publishing more effective information.

2 - Quality 4.0: Recent Trends and Future Research Directions

Kwang-Jae Kim, SeungHyun Choi, Young-Mok Bae, YoungGwan Kim, Ye-won Park, Chanyoung Jang

Quality 4.0 represents a transformative paradigm in industrial quality management, integrating advanced technologies like the Industrial Internet of Things, artificial intelligence, and big data analytics. It enhances product quality and operational efficiency, extending beyond compliance and defect detection to focus on proactive measures, predictive analytics, and continuous improvement.

Despite ongoing debates about the appropriateness of the term Quality 4.0, embracing it implies a shift from reactive problem-solving to a proactive and preventive approach. Hence, research on Quality 4.0 is essential for advancing knowledge, preparing future professionals, and critically evaluating the implications of integrating advanced technologies into quality management practices.

The talk comprises two parts. First, recent trends in Quality 4.0 will be presented, covering the features and benefits of Quality 4.0. Application cases in Korean industries like steelmaking and consumer electronics will also be discussed. Second, potential research directions in Quality 4.0 for the operations research community will be explored, such as developing dynamic quality management models, simulating quality processes in autonomous manufacturing environments, and measuring and optimizing supply chain quality. These directions leverage operations research expertise to address complexities and challenges in implementing Quality 4.0 in manufacturing and supply chain contexts.

3 - Optimizing energy consumption of robotic arm movements based on an enhanced Digital Twin approach

Pavlos Eirinakis, Dimitrios Tsakoumis, Gregory Koronakos

Robotic arms are extensively used in production environments to undertake different tasks such as welding, hemming, etc. Minimizing energy consumption and the corresponding carbon emissions of such robotic systems poses a growing concern for manufacturing. We consider an enhanced Digital Twin approach that facilitates modelling energy consumption and carbon emissions for each specific task the robot performs. Based on this, we present how Data Envelopment Analysis and Pareto optimality can be utilized to evaluate alternative settings of speed and acceleration for point-to-point movements under given trajectories with respect to energy consumption and the time required to perform each task. Then, we utilize Integer Programming to optimize its operation for the whole production cycle accordingly, and discuss how this approach can be applied to operational environments with multiple robots that need to coordinate.

Hydrogen and Electricity Modeling and Regulation I

Stream: Energy Markets

Invited session

Chair: Jens Weibezahn

Chair: Lissy Langer

1 - Impact of imperfect foresight in long-term energy planning: A focus on hydrogen production in Europe and the Nordics

Rasmus Bramstoft, David Garcia Marin, Marie Münster

Energy system models provide insight into future energy trends, with real-life applications for supporting strategic decision-making. In this study, we assess the impact of a rolling planning horizon methodology (i.e. myopic, limited foresight, and perfect foresight over the modelling horizon) in the comprehensive fully sector-coupled European energy system model, Balmore. We compare imperfect foresight i.e. myopic and limited foresight with full decision-making foresight, with a particular focus on the role of hydrogen production in the Nordic region. We apply policy targets and visions, and assess the impact on the design of future energy systems as well as how the role of the Nordic region as a hydrogen exporter is impacted. In addition to analyzing the potential impacts on the design of the energy system, we find considerably longer computation time for solving the comprehensive large-scale energy system with limited or full foresight compared to a myopic approach. Finally, we discuss the implications for energy modellers and decision-makers when assessing future energy systems, which are optimized using different planning foresight horizons.

2 - The cost-competitiveness of offshore hydrogen electrolysis in the North Sea

Kristina Haaskjold, Kari Espegren

Hydrogen has gained significant attention as a potential fuel for the future. It is a versatile energy carrier that can be produced from a variety of low carbon sources and used in different sectors. Norway is uniquely positioned to take advantage of the growing interest, having significant natural resources, including hydropower, new renewable energy, as well as abundant natural gas resources and necessary infrastructure for carbon capture and storage. Furthermore, Norway is strategically located to key markets such as Germany and the Netherlands, which are looking to import hydrogen to meet their energy needs.

Large plans for offshore wind deployment are planned, both in Norway and in Northern Europe, enabling business opportunities for producing hydrogen offshore. Benefits relate to reduced grid expansion, shorter transport distances to Europe and mitigated land use for onshore facilities. Hydrogen produced from offshore wind can also fulfill the requirements as an RFNBO. This study analysis under which conditions offshore electrolysis in the North Sea can be competitive to onshore hydrogen production, from electrolysis and natural gas with CCS, in Norway and in Germany. A mixed integer optimization model is developed using the TIMES framework, with a detailed modelling of the production, distribution and storage of electricity and hydrogen. In addition, the cost-competitiveness of different transport concepts is assessed, including pipelines and transport by ship.

3 - Method comparison for optimal power-to-X plant sizing and operation under wind profile uncertainties

Nicolas Campion, Ioannis Kountouris, David Garcia Marin, Marie Münster

This study centers on off-grid PtX plants powered by wind, whose optimal sizing is challenged by the variability and uncertainty of wind power profiles. This investigation spans various sizing methods, employing deterministic and 2 stage stochastic approaches, and also emphasizes the importance of accurate fuel production cost estimates to derive optimal plant sizing and investment decisions. Results indicate that using a deterministic least-cost investment and operation model with an average power profile year is most likely to lead to accurate fuel production cost estimates. Operational details' influence on cost estimates is minimal, advocating for a linear plant operation model for efficient solving time. In analyzing the optimal sizing and profitability performances, this study shows that the most suitable approach depends on the expected ammonia selling price and the fuel production cost estimates. For scenarios with significantly higher selling prices than cost estimates, a deterministic sizing method with the worst weather year and modeling the flexible ammonia plant as fully flexible proves to lead to the most profitable operation. For scenarios with ammonia selling prices in the same range as cost estimates, using a 2-stage stochastic method with a set of average years leads to the highest profits during operation. While the study focuses on Bornholm, in Denmark, there is acknowledgment of the need for further research to generalize findings.

4 - Fueling the Future: Optimizing Power-to-X Production in Renewable Energy Hubs through Flexible Operating Units

Johannes Giehl, Dana Josephine Hentschel, Jens Weibezahn

The European ambitions for a hydrogen economy require the rapid development and scaling of technology and business models. As frontrunners, the Nordics have the potential to contribute to and benefit from the establishment of hydrogen valleys with the development of energy hubs. Analyzing specific locations is essential to gain insight into the characteristics of optimal production, cost structures, and investments of hydrogen and its derivatives, like methanol. The application of an energy hub model for a case study of producing e-methanol in Southern Jutland helps to obtain specifics on the operation and structure of these business models. The model uses the Spine environment using Mixed Integer Linear Programming to investigate cost-optimal production and investments. Thus, the model helps to obtain specifics of the hub by a detailed representation with variable efficiency rates to improve the representation of flexibility by electrolysis and by-products such as the use of excess heat. An integrated sensitivity analysis enables the evaluation of the impact of regulatory measures and costs on the feasibility and viability of energy hubs. Results show the optimal costs alongside the energy flow of each technology. The evaluation of the energy hub focuses on the leveled cost of the depicted energy carriers. Further development will concentrate on refining investment implementation and integrating technological, and socio-economic aspects identified by the Nord_H2ub project.

The other slots are then given to clients that request an appointment upfront. To determine the number of reserved slots, the (semi-)urgent demand arrivals are often modelled as a distribution with static or seasonal distribution parameters. However, in many appointment scheduling processes, more information becomes available about the urgent demand arrivals over time. An example of these processes is a radiology department, where the number of patients present in the hospital could forecast the required number of emergency scans. In this study, we propose near-optimal scheduling policies that reserve slots for (semi-)urgent clients, using updated information on the arrival distribution of (semi-)urgent clients in the near future. We formulate the sequential decision making problem as a Markov decision process. We test this model on a Dutch real-life case study in the neurology department of Isala Clinics, Zwolle. This neurology department implemented a brain rehabilitation program in combination with an e-coach for stroke patients, where we can use the number of active patients in monitoring to forecast the number of semi-urgent requests for outpatient appointments. We discuss first results on this practical case study and theoretical instances, and present managerial implications of our near-optimal policies.

2 - Optimising Resource Allocation for a Cervical Cancer Screening Program

Francisco Ballestin, M. Angeles Pérez, Sacramento Quintanilla, Javier Villena

Cervical cancer, responsible for over 300,000 deaths in 2020, ranks as the fourth most common cancer. In 2018, the World Health Organization introduced a strategy to partially eradicate it, emphasizing national screening programs to identify the human papillomavirus (HPV), the primary risk factor. A region in Spain have planned to implement comprehensive population-wide screening. This study examines optimization challenges within this program, including HPV detection tests and cytology screenings. While HPV tests are conducted in hospitals, samples and cytologies are collected at community health centers (CHCs) or homes. Midwives at CHCs may need additional hours to attend to patients. Critical resources in this program are the machines in hospitals to process the tests and the midwives. The optimization problem can be modeled in three phases. The first phase selects the hospitals to process the tests, assigns each CHC to a hospital, and calculates the extra cost of midwives in each CHC. The second phase determines the number of tests each CHC sends weekly to their hospital and establishes the program's start and end dates in each CHC. Finally, the third phase calculates how many patients to contact weekly in each CHC to meet the conditions of the second phase. Computational tests using real data validate the models.

3 - Cluster analysis of treatment plans of rehabilitation patients

Maik Overmars

We perform a cluster analysis on treatment plans of rehabilitation patients. Rehabilitation patients receive multidisciplinary care during treatment, which allows treatment plans to be customised to each patient. We cluster patients with similar treatment plans with the goal of standardising these plans and to make predictions for new patients. We aim to use the clustering model as an input for capacity and planning models. We partition each treatment plan into patterns based on decision moments where the doctor decides how to continue the patient's care. The patterns are multivariate count data, as we count the number of appointments per discipline over the duration of the pattern. We use finite mixture methods to cluster the patterns. Each cluster is modelled as a multivariate Poisson distribution. Given a number of clusters, we use Expectation-Maximization to find the optimal parameters for the model. We use the Bayesian Information Criterion to optimise the number of clusters. We analyse the treatment plans, now sequences of patterns, using a non-stationary Markov chain. The transition probabilities are estimated from the clustered data. Subsequently, we calculate the probability of a treatment plan to identify common treatment groups. Finally, we show the validity of the clustering model by simulating new patients and comparing to the actual data. Our method is used by Reade rehabilitation centre in Amsterdam to support the development of standard treatment plans.

Wednesday, 12:30-14:00 - Room: 11 (building: 116)

Capacity and treatment planning in healthcare

Stream: OR in Health Services (ORAHS)

Invited session

Chair: Erik Demeulemeester

1 - Optimizing dynamic reserved resource capacity in appointment scheduling with elective and semi-urgent patients

Jedidja Lok - Visser, Gina van Vemde, Heleen den Hertog, Jan Gerard Maring, Gréanne Leefink

In appointment scheduling, it is a common practice to reserve a number of slots for (semi-)urgent demand arrivals, that require service quickly.

4 - Emergency surgery allocation: Simulation-optimization approach incorporating scheduled elective surgeries under a hybrid emergency strategy

Chao Pan, Erik Demeulemeester

A sudden surge in emergency surgeries strains the critical and limited resources of the operating room (OR). Relying solely on human judgment for emergency surgery decisions may worsen congestion, leading to potential delays or cancellations of both emergency and elective surgeries. In the worst case, if the initially allocated hospital lacks capacity, the patient may face a second transfer, causing additional treatment delays. To address these risks, we develop a stochastic mixed-integer programming model for emergency patient allocation with a hybrid emergency surgery strategy. We then design a simulation-optimization approach to assess the expected maximum capacity for accommodating emergency surgeries. Our approach expedites decision-making in urgent cases, allowing decision-makers to make more rational choices swiftly. Specifically, we propose an improved sample average approximation method with a stopping rule for single-hospital cases, integrating it into the optimal computing budget allocation algorithm for multi-hospital settings. To demonstrate the efficiency of the proposed algorithms, we conduct experiments with real data from a 3A hospital in China. Our results illustrate the robustness of our methods through a sensitivity analysis of internal factors (overtime length), external factors (release time of emergency patients), and expected elective surgery durations. Additionally, we highlight the benefits of collaborative decision-making in multi-hospital setting.

Wednesday, 12:30-14:00 - Room: 12 (building: 116)

Scenarios and foresight practices: Behavioural issues III

Stream: Behavioural OR
Invited session

Chair: Martin Kunc

1 - Biased Foresight: A Facilitator's Playbook

Megan Crawford

A series of lab and field studies were conducted with managers, executives, and postgraduates to test the hypothesis that priming effects exist within any given scenario planning workshop (Crawford, 2021). The studies show that priming scenario practitioners with real-world, yet biased views of the external business environment can significantly alter how they view the future, scenario development, and implications for action. Early indicators also suggest some of these biases may be internally consistent. If true, biases based on priming effects suggests potentialities for both facilitated nudging (Bryson, Grime, Murthy & Wright, 2016; Crawford & Wright, 2024) and predictive modelling (i.e. machine learning and AI; Spaniol & Rowland, 2023). These empirical studies are part of a larger grounded theory investigation. Results support three key claims. First, all scenario planning workshops are susceptible to implicit influences. Second, there may be as much consistency as inconsistency in biased scenario thinking and foresight across teams. Third, facilitators need to understand these variabilities in order to help advance meaningful strategies.

2 - Using ChatGPT in Foresight Fieldwork Pedagogy to Address the Preparedness Paradox by Mitigating the Over-optimism and Normalcy biases

Rui Goncalves, Matthew Spaniol, Nicholas Rowland, Niels Rytter

This pedagogy-methodology paper addresses the challenges of preparing students for foresight fieldwork using AI. Foresight students engage with innovation forecasting, scenario planning, and technology roadmapping, applying them practically. Yet, universities hesitate to

involve early career students with real-world stakeholders in fear of reputational risk. Teachers of these tools will often underestimate the role that their own experience has in their teaching, leaving students vulnerable to mistakes.

This experience bias influences preparedness. Effectively mitigating a risk, diminishes its perceived severity, and individuals who over-prepare may be disappointed when nothing goes wrong because they overinvested in preparing, reducing the perceived value of preparation. Moreover, overconfident individuals underestimate the likelihood of failure, assuming normalcy as the norm, possibly dismissing threat warnings.

Using foresight pedagogy as a case study, the paper proposes an approach to fieldwork preparation, that incorporates ChatGPT in a "role-play" as stakeholder, for lowering risks, addressing cognitive biases, and emphasizing the importance of foresight in undergraduate education. We argue these tools can be used to develop futures literacy skills in controlled research settings, scalable to large classes and diverse case studies. There is potential for this approach to extend beyond future studies, aiding preparation for general community engagements.

3 - Strategic foresight: Combining human creativity with analytical rigour

Carolina van Weerd

Within the defence and security domain, the need for foresight (in order to be able to anticipate trends that will impact the future security environment) is increasing due to the complexity of the changing world around us. Although there are forecasts supported by quantitative analyses, foresight is a discipline in which expert judgement remains central. Therefore we advocate a symbiosed approach of human creativity combined with analytical support. TNO's VISTA (View on Strategic Anticipation) toolkit allows to combine more analytical rigour with human creativity in foresight. The toolkit provides tools to policymakers and analysts with regards to foresight in the defence domain, based on seven steps. These steps do not need to be taken sequentially, nor are they always needed depending on the scope of the foresight case. The presentation of this paper will address the individual steps of our VISTA toolkit, including the way we combined input from analytical methods, scientists and military experts. Special attention will be given to elements that distinguish our toolkit from other, frequently used approaches: (1) a technology focus as starting point, (2) an integral approach, by not only looking at trends in isolation, but to explicitly relate trends with one another throughout the entire DESTEP spectrum and (3) a more detailed insight in possible future security challenges by adding a regional perspective to global future world scenarios.

4 - Assessing responsible anticipation over time. The factual and symbolic sides of future-oriented practices

Anne Marchais-Roubelat, Fabrice Roubelat

Assessing responsibility and irresponsibility in anticipation practices, this research questions future-oriented organizational and personal behaviours over time from both factual and symbolic perspectives (Marchais-Roubelat, 2012). Together with the concepts of responsible futures (Arnaldi et al, 2020, Fuller and Roubelat, 2021) and of responsible foresight (Tonn, 2018, Van der Duin, 2019), the one of responsible anticipation introduces the stance of responsibility in future-making activities. As a commitment to action (Fuller, 2017, Marchais-Roubelat, 2021), anticipation offers critical viewpoints to assess the responsibility of future-oriented practices in a principle of action for situating acts, their effects and their assessments from multiple moving roles over time. Supplementing axiological and deontological dimensions of anticipation (Danaher, 2021), the principle of action stresses the factual and the symbolic sides of commitments, of their effects, as well as of their assessment. From the longitudinal study of the sustainability of nuclear energy in anticipation practices from 1950s to present, we suggest that this principle of action be part of a critical approach to assess the responsibility of anticipation practices. Such a responsible anticipation faces the gaps between future and past or present assessments and invite to introduce the risk of anachronism to question responsible or irresponsible behaviours.

1 - Novel Mathematical Optimization Models for Explainable and Fair Machine Learning

Ksenia Kurishchenko

In this presentation, I give an overview of my Ph.D. dissertation about enhancing explainability and fairness in Machine Learning (ML) via the Mathematical Optimization approach. The use of ML to aid Data-Driven Decision-making is increasing dramatically. The wide availability of ML algorithms brings important advantages, such as the improved accuracy of decisions and the reduction in the resources required to make them. Despite excellent accuracy, state-of-the-art ML tools are effectively black boxes that complicate model trustworthiness and may provide unfair outcomes. In my Ph.D. dissertation, I address this issue and model the trade-off between accuracy and transparency.

2 - Machine learning at the service of meta-heuristics for solving combinatorial optimization problems

Maryam Karimi Mamaghan

In this talk, I am going to present my academic profile and introduce myself to the EURO community in order to initiate possible future collaborations. I will then talk about my research interest and my current research work which is on the integration of machine learning into meta-heuristic algorithms to solve combinatorial optimization problems. I will give an overview of the different ways where we can integrate machine learning into meta-heuristic algorithms.

3 - Artificial Intelligence to Improve Decision-Making Frameworks

Fatima Ezzahra Achamrah

My research operates at the cutting edge of integrating operations research (OR) with artificial intelligence (AI), tackling real-world combinatorial optimization problems across both deterministic and stochastic settings. With a special focus on vehicle routing problems, I leverage state-of-the-art AI methodologies to improve decision-making frameworks. My ambition is to make a meaningful contribution toward enhancing the sustainability and resilience of businesses in a world that is ever VUCA, rapidly evolving, and increasingly interconnected.

Currently, I am engaged in several research that seek to harness the synergy between AI and OR. These projects are dedicated to the design and development of intelligent decision support systems that streamline operations and adeptly manage disruptions within cyber-physical systems.

Looking ahead, my research trajectory is set to explore broader and more complex systems. I am particularly enthused about investigating how OR can intersect with ground-breaking technologies, such as Generative AI. This exploration is driven by the vision of advancing intelligent systems that are not only capable of self-optimization and innovation but are also sustainable and resilient against the backdrop of global challenges.

Chair: Alfaima L. Solano-Blanco

1 - Including Sustainability into the Menu Planning Problem using a Wierzbicky Achievement Function

Francisco Martos-Barrachina, Laura Delgado Antequera, Monica Hernandez

The Menu Planning Problem (MPP) has gained increasing attention in recent years, driven by the need to address the complex interplay between nutrition, cost, palatability and environmental sustainability in our diets. This work presents an approach to fully incorporate these considerations using a Wierzbicky Achievement Function (WAF). The MPP is a multi-objective optimization challenge that aims to generate daily menus that are not only nutritious and affordable but also palatable and environmentally sustainable. Traditional approaches have focused primarily on cost and nutritional aspects, often neglecting the environmental impact of food choices. However, there is a growing urgency to integrate sustainability into the MPP. This holistic approach results in a tri-objective problem that is optimized by using a WAF, a versatile tool that enables the simultaneous optimization of multiple conflicting objectives, to balance the trade-offs between cost, palatability, and environmental impact effectively. By assigning a wide range of weights to each objective, we can find menus that represent a diverse level of compromise between the objectives. Our research shows the effectiveness of this approach by generating an extensive Pareto Front of solutions, offering a spectrum of menu choices that cater to different sets of preferences. This study provides a valuable framework for incorporating multiple considerations into the MPP, paving the way for more responsible dietary choices.

2 - Quadratic Optimization for Sustainable Agriculture - A Study of Mixed Cropping Systems

Edhem Sakarya, Sonja Rohmer, Rolf Van Lieshout, Tom van Woensel

Mixed cropping systems present a promising solution to conventional agriculture by combining multiple crops within one field, thus increasing biodiversity and soil health, yet pose new planning challenges in terms of plant assignment and crop scheduling. To address this issue, we propose a novel decision problem in which crops need to be assigned to different farms and fields over time, taking into consideration a range of diverse factors, including plant interactions, field characteristics, and growth conditions, as well as the demand and geographical location of the customers. In this research, we formulate this problem as a mixed-integer quadratically constrained optimization model aimed at maximizing the total yield and propose a column generation-based approach to solve larger instances. Preliminary results show that our approach outperforms commercial solvers in terms of speed and solution quality. In addition, we present a managerial analysis on the effects of companion planting and the broader implications for farmers, enriching the discussion on mixed cropping systems and sustainable agriculture.

3 - Sustainable crop planning for mixed cropping systems - An optimisation approach

Alfaima L. Solano-Blanco, Sonja Rohmer, Tom van Woensel

Playing a vital role for global food supply, agriculture contributes significantly to current challenges such as biodiversity loss and greenhouse gas emissions. The pursuit of sustainable agriculture aims to find a balance between food production, environmental conservation, and financial viability. Strip cropping presents a promising avenue, in this context, by organizing farmland into smaller plots of different crops to enhance their resistance to pests, increase biodiversity and improve overall soil health. However, at the same time, simultaneous crop management poses operational challenges that prevent the implementation of strip cropping at a large scale. The use of broader strips can decrease these implementation barriers for farmers yet may dilute the ecological benefits by reducing interactions between adjacent crops. These trade-offs complicate the process of devising efficient strip cropping strategies. The aim of this research is to support farmers in this process through the development of a decision support tool. For this purpose, we propose a crop planning model which integrates crop selection and

land allocation decisions under consideration of both spatial and temporal diversity. By determining ideal strip widths and cropping schedules, the model steers farmers towards strip cropping practices that are both economically viable as well as ecologically favorable, thereby promoting a sustainable future for agriculture and global food supply.

1 - Identify the most influential employees in Covid-19 Pandemic by A stochastic MILP influence maximization

Mohadese Basirati, Saeed Najafi-Zangeneh, Mireille Batton-hubert

Managers seek ways to survive pandemic situations to avoid huge financial losses. Preventing staff from infecting each other plays a prominent role in survival. To do so, the infectious among employees should be modeled at first. Secondly, the members who directly or indirectly infect the maximum number of other employees are identified. This problem is considered as an instance of Influence Maximization (IM) general problems. We use a Mixed Integer Linear Program (MILP) analytical optimization for IM problem. The MILP optimization guarantees the global optimal solution. However, due to the uncertain nature of influence, the IM problem is formulated as a stochastic optimization based on a limited number of scenarios. Therefore, the whole stochastic nature of the influence process may not be captured. It is of high importance to check whether the number of scenarios used in stochastic MILP is adequate. To do so, the result of the optimization is simulated with numerous scenarios to evaluate the gap between the objective function and the exact expected value. The proposed stochastic MILP methodology is examined on a company with twelve employees. The efficiency of the method and adequacy of scenarios are then discussed.

2 - Decentralized vs centralized optimal strategies for Covid-19 control with compliance issues

Laurent Alfandari, Debajyoti Biswas

We design a Mixed-Integer Linear Programming model for minimizing Covid-19 infections and deaths over a given horizon of several weeks. We allow two different strategies: centralized decisions applying homogeneously to all citizens at the national level, or decentralized decisions that can vary across regions or cities having different initial situations and risks. The decisions to make are the level of Non-Pharmaceutical Interventions (NPIs) implemented each week, like lockdowns, travel bans, school closures, or combinations of them. Shortages in doctors and hospital beds are considered in the model. Beyond the epidemic model that estimates the number of infections each week, one key aspect of this study is, in the decentralized scenario, the degree of compliance of the population facing more severe restrictions. Our results on real data show from which level of compliance the decentralized strategy starts to outperform the centralized strategy, under the same severity budget over the whole horizon. Compliance has been shown in previous studies to be decreasing in time, hence several kinds of compliance functions are considered to get robust results. Our results are also analyzed with or without the presence of vaccines.

3 - Fair and Effective Vaccine Allocation During a Pandemic

Eda Yücel, Gunes Erdogan, Sibel Salman, Parinaz Kiavash

This study introduces a novel model addressing the Vaccine Allocation Problem (VAP), focusing on distributing vaccines across different population locations over multiple pandemic periods. It incorporates disease progression and vaccination effects to minimize total expected mortality and location-based mortality inequalities while

considering constraints like vaccine supply and healthcare capacities. Utilizing an extended Susceptible-Infected-Recovered (SIR) epidemiological model, the VAP is formulated as a nonlinear mixed-integer programming problem and solved using the Gurobi solver. Through a series of scenarios spanning 12 weeks in the UK, the study highlights the significant impact of vaccine availability and disease spread parameters on optimizing vaccination strategies.

4 - Multi-feature SEIR model for epidemic analysis and vaccine prioritization

Hoda Bidkhor

The SEIR model has become a valuable tool for studying infectious disease dynamics and predicting the spread of diseases, particularly concerning the COVID pandemic. However, existing models often oversimplify population characteristics and fail to account for differences in disease sensitivity and social contact rates that can vary significantly among individuals.

To address these limitations, we have developed a new multi-feature SEIR model that considers the heterogeneity of health conditions (disease sensitivity) and social activity levels (contact rates) among populations affected by infectious diseases. Our model has been validated using data from the Centers for Disease Control and Prevention on COVID cases in Allegheny County.

In addition, we have used our multi-feature SEIR model to propose and evaluate different vaccine prioritization strategies tailored to the characteristics of heterogeneous populations. We have formulated optimization problems to determine effective vaccine distribution strategies. We have designed extensive numerical simulations to compare vaccine distribution strategies in different scenarios.

1 - A method for huge scale maximum covering facility location problems with an application to water well placement in West Darfur

Britt van Veggel

In the analytical context of addressing humanitarian issues, huge-scale facility location problems play an important role. Whether it comes to finding locations for schools, hospitals, or water wells, these problems often involve many demand locations and many potential facility locations. Solving such problems using traditional methods quickly becomes intractable, or even impossible due to large memory requirements. We propose a decomposition approach to efficiently solve huge-scale problems in an exact way by clustering the demand points, solving subproblems for each cluster independently, and combining solutions of subproblems by solving a integer programming problem. Clustering takes advantage of the spatial separation of demand locations to address subproblems independently, guaranteeing optimality. Optionally, heuristic subclustering can be used to further divide clusters. When subclustering is used, bounds on optimality gaps are provided, offering quality guarantees about obtained solutions. We demonstrate the effectiveness of the proposed approach with a case study, which is done in collaboration with the 510 team of The Dutch Red Cross, involving the placement of water wells in West Darfur (Sudan). Solutions for capacitated and uncapacitated problems are obtained within reasonable computation times while providing optimality guarantees where appropriate.

2 - Optimal floor price for e-auction of a seasonal crop

Sundaravalli Narayanaswami

A Miniratna company of the Government of India, under the Ministry of Textiles (ministry, henceforth) has been serving in the field of marketing of cotton for last five decades. As a sovereign function of Government of India, the organization undertakes Minimum Support Price (MSP) operations to safeguard the cotton farmers from any distress sale and offers its cotton stocks through e-auction on regular basis to meet out the demand of quality cotton to domestic textile Industry at competitive rates. In this paper, an objective model to decide the variety-wise optimal floor price of daily e-auction of cotton is developed and presented. Before the model was proposed and developed, a team of subject matter experts and top management of the organization considered the (i) variety-wise prevailing prices of cotton in Indian market, (ii) general price behaviour of international market and (iii) previous days' variety-wise sale rates over & above the floor price and decided the floor price for daily auction. The organization currently uses the optimal floor pricing model to scientifically determine the floor price for the 15 odd cotton varieties grown in India and traded globally in the e-auction mode.

1 - Large-Scale Binary Matrix Optimization for Multi-Microgrids Network Structure Design

Rui Wang, Gang Zhou, Bo Jiang

The Multi-Microgrid Network Structure Design Problem (MNSDP) is a binary matrix optimization problem that aims to minimize the cumulative length of preset power lines in a multi-microgrid system, while satisfying specific constraints. This problem is of great significance for improving the utilization rate of renewable energy sources and the stability and resilience of power systems in remote areas from the central grid. Due to the large-scale, sparse and nonlinear characteristics of this problem, traditional optimization methods are difficult to obtain satisfactory solutions within a reasonable time. This paper proposes a mathematical model of the MNSDP, incorporating three types of nodes with different reliability requirements. The paper also introduces a benchmark test suite, MNSDP-LIB, based on real-world scenarios, to evaluate the performance of algorithms. To solve the MNSDP, the paper develops a new matrix-based constrained differential evolution algorithm, LBMDE, which employs a binary-matrix-centric DE operator and an enhanced feasibility rule-based environmental selection strategy. The paper conducts extensive experiments to compare LBMDE with several state-of-the-art evolutionary algorithms and a commercial solver on MNSDP-LIB and other binary matrix optimization problems. The results demonstrate the superiority of LBMDE in terms of solution quality and computational efficiency, as well as its contribution to advancing renewable energy and microgrid technologies.

2 - A Binary Expansion Approach for the Optimal Demand Response in Large and High Altitude Water Transportation System

Denise Cariaga, Miguel Anjos, Alvaro Lorca

Demand response for water networks is an optimisation model that determines which water pumps will be turned on or off at each time period according to a dynamic electrical tariff. This problem is important in mining due to the high power consumption of water pumps, as well as the complicated dynamics of water flows and the power market. The problem faces difficulties from: i) the nonlinearities of the equations for the frictional losses along the pipes and pumps, which make

the problem a nonlinear mixed-integer model, ii) the many possible combinations of pressure head and flow rates, which quickly lead to high computational costs, and iii) the uncertainty from energy prices and water demand. These limitations prevent the problem from being solved to optimality in a reasonable computational time in water systems with more than two pumps and reservoirs. Therefore, we develop new optimisation models for the demand response in large and high-altitude water transportation systems that use a binary expansion approach to efficiently account for the existing nonlinearities by reducing the computational difficulties while maintaining an excellent representation of the physical phenomena involved. We also tested this approach in different network topologies and case studies, and we conclude that the method significantly reduces the computational time for solving the problem with high precision, which can be relevant for the daily operation of real-world water transportation systems.

3 - Exact and metaheuristic methods for multi-objective energy aware hybrid flow shop scheduling problem with blocking and sequence-dependent setup times

Ahmed Missaoui, Cemalettin Ozturk, Barry O'Sullivan

The manufacturing sector is considered one of the most significant consumers of energy. Given the energy crisis, manufacturing industry is paying increasing attention to energy-efficient scheduling as a short/medium-term strategy for reducing energy consumption without requiring significant investments. In this paper, the Hybrid Flowshop Scheduling Problem with Blocking Constraints and Sequence Dependent Setup Times (BHFS-SDST) is addressed for the minimization of makespan and total energy consumption (TEC). A novel constraint programming (CP) model as an exact method is developed and its performance is compared with another exact method, mixed-integer linear programming formulation (MILP) and a multi-objective iterated greedy (MOIG) metaheuristic. The effectiveness of the proposed approaches is tested with randomly generated small, medium, and large benchmarks. Computational experiments demonstrate the efficiency of the developed methods in solving the BHFS-SDST problem.

4 - A heuristic for fitting piecewise-linear models of bivariate functions with simplices and its application to an industrial use case

Victor Ruela, Paul van Beurden, René Hofmann, Felix Birkelbach

A common approach to solving MINLP problems is to convert them to a MILP using piecewise-linear (PWL) models to approximate the nonlinearities. However, finding a PWL approximation that respects an error tolerance with the minimum number of linear pieces is a challenging task. Moreover, available methods are complicated and difficult to implement. This paper addresses finding error-bounded PWL approximations for continuous and smooth bivariate functions. The method proposed is an easy-to-implement heuristic applied for the case of a triangulation generated over rectangular grids. On each iteration, a nonlinear programming problem is solved to adjust the placement of the linear pieces to minimize the approximation error. Then, we increase the number of breakpoints for the variable with maximum error reduction potential. For an industrial use case from the steelmaking industry, the ladle dispatching problem with refractory temperature control, we show how applying this heuristic can reduce the complexity of the resulting MILP while respecting a strict approximation error requirement. The heuristic achieved an average reduction of 67% in the solution time of the MILP with an average 34% reduction in the approximation error.

1 - Tackling hard problems: on the evolution of operations research

Laura Albert

As we think about what impact we would like operations research (OR) to have on the world, it can be helpful to look to the past for guidance and inspiration. This talk overviews the early stages of operations research becoming a discipline and academic field of study following World War II. In this talk, I will introduce "fun facts" about OR history, including the piece of OR history that inspired a scene in the film *Good Will Hunting*. I will also discuss early attempts to define the field of operations research, drawing upon the writings of Philip McCord Morse. The young field of OR experienced some growing pains, when some leaders in the field expressed their concerns about the demise and possible death of OR. Ultimately, OR flourished in the following decades. A theme of the talk is that various efforts taken to tackle hard problems defined the field of OR, opened up fruitful areas for exploration, and guided the evolution of OR.

2 - 75 years of the world's first OR journal

Graham Rand, Martin Kunc

In 1950, the world's first OR journal, the *Operational Research Quarterly*, was published. Hence, 2004 sees the 75th volume of, what is now, the *Journal of the Operational Research Society*. This talk will discuss the origin of the journal, and changes in editor, frequency, publisher and content during these 75 years. A current editor-in-chief will discuss JORS' 75th volume and future plans.

3 - Exploring the innovative nature of Forrester's 'Industrial Dynamics'

David Lane

This talk reflects on the 1961 publication of Jay Forrester's 'Industrial Dynamics', the founding text of the field of System Dynamics. It considers the circumstances that catalysed Forrester and explores the influences and published antecedents of the book. It presents a range of contemporary reactions, drawn from perspectives inside and beyond OR. It explores the ways in which the ideas in 'Industrial Dynamics' - ID - relate to other fields. From the perspectives of Systems Science, OR and Problem Structuring Methods/Soft OR, it explores: commonalities in intellectual provenance; similarities in central ideas; influences that the book had on the field. Via a biographical sketch, the talk argues that the provenance of the ideas in ID can be seen to be grounded in, and exemplified by, the life of Forrester himself. It closes by drawing three conclusions. (1) The book continues to offer methodological challenges to OR, to contribute to debates on the nature and identity of OR. (2) It vivified an important thread of feedback thinking, providing a vehicle by which abstract ideas can be put to practical use. (3) ID anticipated developments in PSMs/Soft OR - meaning that the book's ideas add weight to the case made by those in this area. In other words, whilst ID continues to be source and origin for the core ideas of the System Dynamics field, it offers bold and innovative ideas for all those interested in using practical techniques to solve messy, real-work problems.

4 - The life and work of Harry M Markowitz

Josh Fogg

Harry M Markowitz (1927-2023) was a man who lived many lifetimes. An American Jew born in Chicago, his childhood ran through the turmoil of both the Great Depression and World War II. He went on to do much pioneering research, for which he won both the Nobel and John von Neumann prizes.

Within OR, he's recognised as the father of Modern Portfolio Theory for his work on mean-variance analysis. Not content to define just one field, he's also known as the grandfather of Behaviour Economics for his ideas on behaviour under risk. Including and beyond these, he was a prolific researcher across economics, mathematics, and computer science.

Markowitz' collaborators in that are a "who's who" of 20th century scientists: Dantzig, Friedman, and Sharpe among many others. His

academic career took him to institutions the world over, with positions at City University of New York, London School of Economics, and the University of Tokyo. This intertwined with a robust career in industry, including stints at RAND, IBM, and CACI, where he had a significant impact. His life spanned a century of tremendous development, filled with incredible (and at times unbelievable) history and many valued contributions to the sciences.

In this talk we look over Markowitz' life, reviewing the discoveries he made along the way and the influence he had on the direction of so many fields.

1 - An Approximate Dynamic Programming Approach for Managing Vaccine Distribution with Uncertain Supply and Limited Resources

Peiyan He, Junlong Zhang

We study the vaccine distribution problem over a three-echelon network during a sudden pandemic outbreak. We consider uncertainties in vaccine supply due to delays in production, disruption in global supply chain or lockdown policies in the early phases of the pandemic outbreak. We also consider limited resources including cold trucks for vaccine transportation and healthcare workers for vaccine administration. The problem is to dynamically allocate these limited resources over the network such that vaccine can be transported and administered in a timely and cost-effective manner. We formulate a dynamic programming model for this problem and propose solution algorithms based on approximate dynamic programming. We conduct a case study on a vaccine distribution network in Iran and report computational results that demonstrate the effectiveness of our solution approach over two benchmark approaches.

2 - COVID-19 quantitative processes and vaccine inventory policies

Bela Vizvari

COVID-19 is the first epidemic in the history of mankind such that daily data are available in all countries. It makes possible to get an understanding of the quantitative processes of pandemics.

A pandemic is a saturation process. This fact makes it possible to find good approximations of the quantitative processes of the pandemic including the total number of cases, and the number of vaccinations. The method is applied to 18 countries. The approximation has good quality even in the case of multiple waves.

The procurement of vaccines is made on the level of countries. Based on the obtained approximation, inventory policies are elaborated for countries. The first model minimizes the total inventory cost in the case of deterministic consumption and delivery.

The second model keeps the probability of shortage under a prescribed level in case of stochastic delivery. This model is a generalization of the so-called Hungarian inventory model.

Rich countries purchased huge quantities from vaccines. They could not use completely all these vaccines. On the other hand, poor countries could not get enough vaccines. Therefore, they repeatedly infected the population of rich countries. It was a reason of the multiple waves. It is assumed in the third model that one producer delivers to several countries. A fair distribution is the aim of the model with minimal total shortage.

1 - A New Integrated Assessment Framework for Energy-Economy-Environment Modeling: Insights from Coal Phase-out in the Turkish Power Sector towards Net-zero Emission Targets

Ebru Voyvoda, Bora Kat, Umit Sahin, Saeed Teimourzadeh, Osman Bulent Tor, Alp Erinc Yeldan

Power sector plays a crucial role towards decarbonization for many economies, especially in line with the net-zero targets to limit global warming by 1.5 Celsius degrees. Technical constraints intrinsic to the sector, penetration of new technologies, investment and operational costs, as well as its links with the rest of the economy make the power sector a complex system to analyze. Although there are numerous studies to integrate bottom-up power sector technology models with top-down macroeconomic models, this study is the first attempt to link the three separate and interrelated models within a single framework: an electricity market simulation model, a generation expansion planning model, and an applied general equilibrium model. The proposed framework is implemented to analyze alternative scenarios aiming at successful phasing-out of coal-fired power plants in Turkey. The results suggest that, given the existing capacity and potential of renewables, Turkey can achieve her coal-phase out by early 2030s. The results also show, while installed capacity and generation of coal-fired power plants are reduced, real GDP and electricity demand could be maintained; and the CO₂ emissions from power sector could be reduced by as much as 50% in 2030 compared to their 2018 level.

2 - Coordinated Optimization of Water-Energy System Operation

Patrick Martin, Jannik Haas, Wolfgang Nowak

Water supply systems are critical infrastructure and will be forced to adapt to threats posed by climate change. In literature optimization of these systems is often done for either steady state, or single source one year operation. Most studies focus on the water side of the operation while incorporating mostly limited energy aspects. Therefore, fully joint planning of water-energy systems is still incipient, as is operation under a fully renewable regime. In this work, we use multi-objective optimization methods to model water-energy systems with a high temporary resolution. We focus on the operation of existing water supply systems and expansion planning to optimally incorporate renewable energies by striking the balance of less efficient operation against cheaper and cleaner energy sources and storage. This is done for different operation regimes, including a wide range of prediction horizons, from greedy short-term decision making comparable to current operation up to global (in time) optimization as a reference bound. We validate the model of the water supply system using data provided by our German project partner, Landeswasserversorgung. In conclusion, we show how the operation of existing water supply networks should change and how to adapt the network to integrate renewables in a combined water-energy system in preparation for our future work on long-term predictions using simulations of future climate scenarios.

3 - Emissions Uncertainty, Technology and Optimal Commuting and Leisure Demands

Ioannis Paraskevopoulos

In this paper, we offer a theoretical framework to rationalize choices of commuting and traveling for leisure conducted by individuals under uncertainty about the future level of emissions. The main focus is analyzing technology's role in this process. The model is estimated for a sample of surveyed individuals across US counties during the years

2017 and 2018. The role of technology is measured through the availability of fixed broadband and fiber-to-the-home for each individual. We find positive elasticities of substitution suggesting that as the cost of commuting increases, the demand for broadband services increases. This implies that individuals are substituting commuting with activities that require broadband such as working from home and therefore digital technology is an emission reducer and produces productivity gains in travelling for work and leisure. More commuting time for work will cause an increase in emissions volatility across counties, and the total effect on expected emissions will be positive as individuals do suboptimal consumption of the two activities.

4 - Location- and Volume-Based Subsidies for CCS: A Game-Theoretical Approach

Adrien Nicolle, David Lowing

Despite being an essential technology in industrial decarbonization scenarios, Carbon Capture and Storage (CCS) struggles to reach large-scale deployment. To tackle this issue, public entities have set up numerous funding mechanisms to kickstart the adoption of this technology. However, these mechanisms generally support only the capture stage of the CCS value chain, thus overlooking support for dedicated transport and storage providers. In contrast, this paper develops a distribution rule to allocate a subsidy budget to the entire CCS value chain. First, we derive a cooperative game based on the cost-minimizing pipeline network connecting emitters to storage sites. We find that the Shapley value, typically computationally challenging, is attainable in polynomial time due to the specific structure of our problem. We then define each emitter's subsidy claim from public entities by combining the emitters' network cost shares (i.e., location) with their cost of capturing CO₂ (i.e., volumes). Because public entities may lack sufficient resources to cover all emitters' claims, we turn to bankruptcy theory and apply a division rule known as the Constrained Equal Awards rule, which we normatively justify by axioms relevant to our context. We prove that the spatial dimension substantially impacts the results of the distribution rule. From a policy perspective, our paper's findings suggest that current approaches should not overlook the location of industrial emitters.

New technology for sustainable supply chains

Stream: Circular Economy, Remanufacturing and Recycling

Invited session

Chair: Marcus Brandenburg

1 - A multi-dimensional assessment of circular technologies in agriculture waste management

Patrizia Lombardi, Elena Todella, Timothée D'Amico

Agriculture emerges as a major contributor to global anthropogenic emissions, such as waste production and greenhouse gases, and to resource depletion, such as water and land, requiring a transition from a linear to a circular approach. According to the WWF, the agricultural sector consumes about 69% of the planet's fresh water and the FAO estimates that the livestock sector alone is producing about 14.5% of all greenhouse gas production. Agri-food is among the most relevant manufacturing sectors in Italy. In this context, a large-scale and multi-disciplinary research program has been funded by the National Recovery and Resilience Plan, named AGRITECH, The National Centre for Agricultural Technologies (<https://agritechcenter.it>), with the aim to promote innovation and technology transfer. A large research area of this program focuses on circular waste management and multi-dimensional sustainability assessment. This study is part of this research area and focuses on orange peel waste (OPW) management processes. It proposes a critical review and selection of the KPIs

to assess alternative technologies of OPW management, and a preliminary application of the Analytic Hierarchy Process (AHP) to rank such alternatives.

2 - Carbon Reduction, Blockchain Technology, and Business Model in Online Retail Platforms

Qi Sun, Yumin Fu, Cheng Ma

Online platforms are leveraging its power to foster environmentally friendly supply chains. This study explores the blockchain application and business model decisions in a supply chain with a manufacturer selling through an online retail platform. The manufacturer decides whether to adopt blockchain technology to provide evidence of carbon reduction, aiming to secure an eco-friendly label from a platform, which in turn determines the business model, choosing between agency selling and reselling. We fully characterize the equilibrium decisions and show how they depend on the carbon reduction efficiency, blockchain efficiency, and commission rate. The presence of a carbon reduction manufacturer reduces the effectiveness of using the wholesale price as a lever by itself. Therefore, employing blockchain upon a reselling platform can hurt the manufacturer. We also show that blockchain technology and business mode are complementary, and therefore managers should not ignore the impact of one decision on the other decision even when the latter is not a primary motivation of the former. This study represents a significant stride towards the integration of blockchain in production and underscores collaboration with dominant platforms to offer guidelines for effectively reducing carbon emissions.

3 - Exploring Blockchain Implications in Closed-Loop Supply Chains

Hamed Jalali, Behzad Maleki Vishkaei, Pietro De Giovanni

In the realm of supply chain dynamics, the influence of Blockchain technology has been extensively explored within the forward channel, yet its repercussions on reverse logistics and closed-loop supply chains (CLSC) remain understudied. For instance, Wipro, a prominent multi-billion-dollar technology company, actively employs Blockchain technology to combat counterfeiting challenges within the realm of product returns. This paper addresses this gap by delving into the implications of Blockchain adoption in CLSC.

Focusing on the interplay between a manufacturer and a retailer, our study formulates a Stackelberg game wherein the manufacturer seeks to deploy Blockchain technology to enhance the accuracy of valuing end-of-life returned products. However, this adoption comes with a nuanced challenge—potential customer concerns about privacy and data collection within Blockchain, which can adversely affect the retailer by dampening customer demand.

Moreover, the manufacturer faces a choice between internally managing the collection of used products or outsourcing this task to the retailer. Through analysis of equilibrium strategies, we offer novel insights that contribute to a more comprehensive understanding of the multifaceted consequences of Blockchain integration in closed-loop supply chain dynamics.

4 - Additive manufacturing in the circular economy: a simulation approach

Marcus Brandenburg, Biman Darshana Hettiarachchi, Stefan Seuring

To study the impacts of additive manufacturing (AM) in the circular economy (CE), we develop a causal loop diagram (CLD) that consists of contingent factors which are detected in a structured literature review by systematic analyses of content and contingencies. The CLD is developed further to a simulation model to analyze the system behavior and to investigate core factors of AM and their roles and interrelationships in CE contexts. The findings inform about the (in-)stability of the system and how it can be influenced.

Chair: *Dmitry Krass*

1 - Strategic analysis of e-platform supply chain decisions

Fatemeh Zand

Our study delves into a platform supply chain that comprises a manufacturer and an e-platform, alongside a secondary marketplace. Drawing inspiration from real-world industrial scenarios, we explore the roles of the marketplace and the retailing channel within the e-platform. We outline the optimal operational strategies for this platform supply chain, considering various supplier market encroachment strategies. Furthermore, we conduct a comparison of supplier encroachment strategies, developing an analytical framework to show how to choose the optimal strategy and the critical factors influencing this decision within the platform supply chain. Additionally, we analyze the dynamics of optimal collect and resell strategies for the e-platform, along with the corresponding operational decisions, indicating how the e-platform should adapt its strategies based on the supplier's chosen encroachment strategy.

2 - Optimal Manufacturer Strategies and Government Intervention for AFV Transition under a Distributive Justice Perspective

Wissam EL Hachem

Rising environmental awareness among consumers known as Consumer Environmental Awareness, led to the entry of green products into the car market. This led to the issue of competition between these green and non-green products which has been the subject of research lately. We focus on the pricing and the degree of greenness of a product in competition with an established non-green product while considering government intervention. We build a model with two players, Government and Manufacturer, to focus on government intervention (taxes and subsidies) in the context of transition to Alternative Fuel Vehicles (AFV) under two scenarios. In one there is no Distributive Justice (DJ), and in the other DJ enters by modifying the social pillar in the government's utility to maximize consumer's access to vehicles. The government's tax and subsidy override the manufacturer's prices when determining the dynamics highlighting the decisiveness of government intervention in such a setting. The dynamics of the environmental and economic pillars show tradeoffs which are partially alleviated when we consider DJ. We show that when introducing DJ into the model, there is no Pareto front where all three pillars improve simultaneously and the government's utility remains more or less the same. The manufacturer's profits and consumer surplus exhibit a harmonious relationship whereby they increase together. Finally, the demand for AFV is always cannibalizing the demand for ICE.

3 - Influences of Blockchain Technology on Restricting the Misuse of Green Loans in a Supply Chain

Bo Li, Ruidong Zhao

Nowadays green loans have been widely promoted to support the capital-constrained supply chain under carbon regulation. But, the borrowers in the supply chain may use the preferential green loans for other purposes which are not related to green development. That phenomenon is mainly attributed to the lack of valid information investigation under traditional information technology. Blockchain, as an innovative technology, can provide valid financial information and identify liability in the use of green loans, which is an effective tool to restrict the misuse behavior. But will the high operating cost weaken the advantage of blockchain? To address this question, we consider a supply chain with a supplier and a capital-constrained manufacturer. The manufacturer may misuse part of the green loans to purchase primary components from the supplier. Two operational modes corresponding to no-blockchain adoption and blockchain adoption are designed, in

which the supplier determines the wholesale price, and the manufacturer determines the order quantity under green loans. By comparing the optimal decisions of supply chain members, we put forward and differentiate three types of effects: the carbon regulation effect, the information verification effect, and the blockchain cost effect, which influence the adoption of blockchain technology in the supply chain. In addition, we show that blockchain can restrict the misused amount of green loans and improve the environmental performance.

4 - Technological and Market Response to Environmental Taxation by a Competitive Industry

Dmitry Krass, Anton Ovchinnikov

We consider response to environmental taxation by competing heterogeneous firms producing a commodity good with a polluting by-product (e.g., CO₂). Firms are heterogeneous with respect to production efficiency and have a choice of finite types of pollution control technologies. Firms are faced with fixed plus linear production costs. Cournot competition is assumed. The key research question is the extent to which environmental taxes can be used to induce "green equilibrium" i.e., an equilibrium where all firms select the most environmentally efficient technology. We show that, in general, neither existence nor uniqueness of equilibria are guaranteed and characterize market demand functions under which existence does hold. However, even in this case, the equilibrium may include firms using less environmentally efficient technology choice at any level of environmental taxes. Thus, environmental taxation alone cannot reliably induce green technology choice. However, when coupled with fixed-cost subsidies, both existence and uniqueness of the green equilibrium are shown to hold.

1 - Characterization and NP-Completeness of ATC Tool Indexing Problem without Tool Duplication

Deepti Mohan, Diptesh Ghosh

The evolution of automated machining centers, especially in sectors such as aerospace and automotive manufacturing, has been significantly driven by the adoption of Automatic Tool Changers (ATCs) in computerized numerical control (CNC) machines. These ATCs are pivotal for the efficient execution of diverse machining tasks, facilitating rapid tool changes without manual intervention. Central to enhancing the operational efficiency of these centers is the challenge of optimizing the ATC indexing process. This problem, known as the ATC Tool Indexing Problem, is a challenging combinatorial optimization problem. The ATC Tool Indexing Problem without Tool Duplication is a variant of this problem, which can be formulated as a specialized instance of the Quadratic Assignment Problem, with a distinctive structure in its distance matrix. We present a characterization of optimal solutions to the ATC Tool Indexing Problem without tool duplication. We also show that this problem is NP-Complete.

2 - OWA for Combinatorial Problems with Interval Uncertainty

Werner Baak, Marc Goerigk

The Ordered Weighted Averaging (OWA) method is a popular generalization of robust optimization, which is most commonly applied to combinatorial problems if they have an uncertainty set modeled by a discrete list of scenarios. We introduce a novel approach, OWA for

interval uncertainty, which extends OWA to handle uncertainty represented by continuous intervals. We explore its properties, including its relationship with OWA for discrete scenarios and sample convergence, and present both theoretical results and solution methods.

3 - Some particular combinatorial problem solved using integer partition theory techniques."

Zahra Yahi, Sadek Bouroubi

There is an abundant literature on integer partitions, with diverse applications, notably in computer science and more specifically in the field of image processing. In this paper, we present some new results. In the first part we present the initial result, concerning the enumeration of triangles with fixed perimeter and distinct side lengths and in the second part, we give closed formula of the number of quadrilaterals with different side lengths and a fixed perimeter, achieved through the utilization of integer partitions theory. Intermediate results are provided."Many open problems will be posed for further exploration."

4 - Structured (sub-)symmetry breaking in MILP by variable aggregation

Cecile Rottner

MILP resolution is strongly impacted by symmetries, namely the existence of solutions identical up to a permutation. In this presentation, we focus on MILP with structured symmetries, ie any column permutation of the solution matrix is a symmetry. Various types of symmetry-breaking techniques exist to handle such symmetries, from specialized branching disjunctions, lexicographic ordering or symmetric variables aggregation. We focus on the latter technique which has shown to be very efficient on problems with specific structure, namely featuring the disaggregation property. We study in which case the aggregation technique can be used and how to benefit from its efficiency in more general cases. Case studies on variants of the Unit Commitment problems are proposed.

1 - An adaptive VNS optimization algorithm for order acceptance with scheduling problem in additive manufacturing

Teng Cao

We studied the order acceptance and scheduling problem on a single machine in additive manufacturing (AM) environment, considering a group of part orders with different sizes, profits, arrival date, due date, and delivery deadlines to be decided, manufactured and scheduled on an single AM machine. In our research, the AM machine is modeled as a batch processing Machine, processing part orders in batch sequences. Part orders are either accepted and assigned to a batch or rejected, the accepted orders are subject to dual constraints of time window and processing space. The goal is to maximize total net revenue considering orders revenue, processing costs, and penalties for delayed delivery and order rejection.

In this talk, we : 1. develop an Adaptive Variable Neighborhood Search Algorithm (AVNSA) to obtain a high-quality order acceptance list and part processing sequence which satisfies all technical constraints. 2. present a heuristics methods for initialization. 3. propose 9 kinds of move operators for neighborhood search and 2 kinds of backtracking mechanism to prevent the algorithm from getting stuck in local optima 4. make the comparisons between the proposed AVNSA and several methods in previous research in 135 randomly generated instances.

The preliminary experimental results illustrates that, within shorter CPU time, the AVNSA is capable to obtain better solutions with higher net revenue, fill rate and less delay.

2 - Solving flexible job shop scheduling problems with multiple resource constraints using a unified CP-based solution framework

Grigorios Kasapidis, Dimitris Paraskevopoulos, Yiannis Mourtos, Panagiotis Repoussis

This study focuses on flexible job shop scheduling problems with multiple resource constraints. It introduces a comprehensive approach for modeling various resource types like limited capacity machine buffers, tools, utilities, and work in progress buffers. The proposed methodology involves a Constraint Programming (CP) model alongside a CP-based Adaptive Large Neighbourhood Search (ALNS-CP) algorithm. The ALNS-CP algorithm incorporates long-term memory structures to retain valuable information about individual and paired operations assigned to machines, gathered from high-quality and diverse solutions during the search process. These memory structures aid in formulating additional constraints for the CP solver, and therefore guiding the search towards promising areas of the solution space. To evaluate its efficacy, extensive experiments were conducted on established benchmark sets, comparing the performance of ALNS-CP with existing state-of-the-art methods. Furthermore, new instances of varying sizes were utilized to explore how different resource types impact the makespan. The computational findings highlight the competitiveness of the proposed framework, notably yielding 39 new best solutions across well-known problem instances of the literature.

3 - Instance space analysis of the shift minimization personnel task scheduling problem

Reshma Chandrasekharan, Kimmo Nurmi, Nico Kyngäs, Jari Kyngäs

The shift minimization personnel task scheduling problem concerns the optimal assignment of a multi-skilled workforce to skill-specific tasks and the objective is to minimize the number of shifts utilized. Due to its widespread applications in personnel scheduling, various efficient algorithms have been proposed for this problem which solves most of the benchmark instances to optimality. However, some of these instances remain extremely hard to solve. Various statistical experiments have been conducted to analyze what makes some of these instances hard and as a result, a new set of benchmark instances have been generated which offer a significant challenge to the state-of-the-art algorithms.

In addition, this shift minimization problem translates as the list coloring problem on interval graphs, a classic coloring problem on graphs. Through this study, we also investigate what are those graph properties that significantly affect the difficulty in coloring interval graphs. We observe that various scheduling problems in the literature can be polynomially reduced to the list coloring on interval graphs and therefore, our observations and insights can shed light on what makes certain interval scheduling problems and specifically the subsets of their benchmark instances hard.

1 - Conic Functions: Theory and Applications in Machine Learning

Gurkan Ozturk, Emre Çimen, Zehra Kamisli Ozturk

Polyhedral conic functions, introduced by Gasimov and Öztürk, are defined with graphs depicting convex polyhedra as their level sets. They have become vital in machine learning, particularly for addressing classification problems. Derived by augmenting a hyperplane equation with the l_1 norm, a polyhedral conic function relocates within the space through the vertex point. The PCF (Polyhedral Conic Function) algorithm efficiently separates two sets of points in multidimensional spaces by solving a linear programming subproblem. It computes parameters and yields a function partitioning the space into two regions, thereby separating points effectively. PCFs find utility in classification by formulating error functions to minimize discrepancies between sets. They have applications in image processing and psychiatry, aiding tasks like object recognition and disease identification. Various PCF-based algorithms, like clustering-based PCF and Incremental Conic Functions, use clustering approaches to find vertex points. These extend traditional PCF capabilities by incorporating clustering techniques. Mathematical programming and optimization play a crucial role in PCF algorithms, providing a framework for fine-tuning performance. Their termination in finite steps underscores their efficiency, making them appealing in real-world applications. In conclusion, PCFs offer a versatile approach to classification problems, supported by mathematical principles.

2 - Machine-learning-based policy for the dynamic pricing of substitutable itineraries

Yue Su, Axel Parmentier, Antoine Désir

In the airline revenue management, dynamic pricing for substitutable itineraries presents significant challenges due to the stochastic nature of customer choices. The dynamic pricing problem can be conceptualized as a Markov decision process with the objective of maximizing the total expected revenue over a finite selling horizon. However, the complexity of this model, characterized by its multi-dimensional state and action spaces, makes it computationally prohibitive to solve exactly, even for small-to-medium-sized instances. As a result, classic methods such as dynamic programming prove inefficient to address the dynamic pricing problem for larger instances. In this work, we introduce learning-based policies tailored to dynamic pricing problem of substitute itineraries with the same origin and destination. These policies are encoded by hybrid machine learning pipelines, while taking into account the heterogeneous customer choices. We proposed two different configurations of pipelines, where we have designed tailored training process for each of them. To demonstrate the performance of our learning-based policies, we first benchmark it against the optimal policy obtained from dynamic programming on small-sized instances. Then, we benchmark it against the state-of-the-art approximated policy heuristics on larger-sized instances. In addition, our method can be easily adapted to airline network scenarios, where itineraries of different origins and destinations are included.

3 - Interpretable Ensemble Learners for Explainable Business Analytics

Eren Berk Aytac, Koen W. De Bock, Sureyya Ozogur-Akyuz

Customer churn is a common problem for companies. The problem is that traditional business analytics models, particularly when it comes to predicting customer churn. The core of the issue is that these traditional models don't necessarily align with business objectives. For instance, a typical customer churn model might tell us whether a customer is likely to discontinue service, but it stops short of considering the financial implications of churn. Additionally, algorithms' decision-making processes and outcomes should be understandable and explainable to humans. Rule-based models (e.g. rule ensembles) are among the methods used to provide this level of explainability. In this study, Profit Driven Spline Rule Ensembles Customer Churn Prediction Model has been developed for this problem. The unique aspect here is the profit-driven approach, which ensures that the predictions are aligned with the company's financial goals. Part of this approach involves adapting model performance metrics EMPC to be understandable to humans. By utilizing spline rule ensembles, the model captures complex relationships in customer behavior that standard models might miss. The

Invited session

Chair: [Emilio Carrizosa](#)

Chair: [Sureyya Ozogur-Akyuz](#)

key to the model's success lies in its interpretability. In today's complex decision-making landscape, clarity is very important. The model doesn't just churn out predictions; it provides a window into the 'why' and 'how' of customer behavior, empowering decision-makers with the knowledge to act decisively and effectively.

4 - Incremental Accelerated Hyperbolic Smoothing Clustering Method: Computational Results

Adilson Elias Xavier, Vinicius Layter Xavier

This work considers the minimum sum-of-squares clustering (MSSC) problem, which has an intrinsic bi-level nature and the significant characteristic of being nondifferentiable. To overcome these difficulties, the proposed method adopts a smoothing strategy, which engenders an unconstrained completely differentiable single-level alternative. The proposed algorithm also applies a partition of the set of observations into two non-overlapping groups: "data in frontier" and "data in gravitational regions". The article introduces a novel incremental procedure to produce starting points in an iterative way, which begins with only one centroid, and which adds one cluster centroid at a time. To show the distinct performance of the new algorithm, we perform numerical experiments with a set of thirteen large test problems from the literature. In short, except for a few solutions, numerical results show a high level of performance of the IncAHSCM algorithm according to different criteria of accuracy and speed, in compassion with the best-established clustering algorithms. The accuracy performance can be attributed to the complete differentiability offered by the hyperbolic smoothing approach, as well as, by the strategy to get good initial starting point. The high speed of the algorithm can be attributed to the partition of the set of observations into two non-overlapping parts, which drastically simplifies the computational tasks.

1 - Greenhouse gases levels prediction using artificial neural networks

Hugo Valadares Siqueira, Thiago Antonini Alves, Tiago Emmanuel Nunes Braga, Ricardo Godoi, Yara Tadano

The increase of greenhouse gas (GEE) levels alters the energy balance between the atmosphere and the Earth surface, leading to temperature changes that modifies the atmosphere chemical composition. Then, the air pollution represents one important index to be analyzed, as it is directly related to climate changes mitigation goals. The development of a public tool that allows future predictions of potential GEE environmental impacts are essential to the economy, environment and social and health aspects. In this sense, the development of systems for monitoring, forecasting, and controlling emissions plays an important role. The main objective of this research is to apply trainable and non-trainable combination methods for air pollution forecasting in Brazil. Trainable ensembles based on Artificial Neural Networks (ANN) and linear regression are compared with non-trainable combinations, single ANN, and linear statistical approaches. Different models are considered so far, including Autoregressive Model, Autoregressive and Moving Average Model, Infinite Impulse Response Filters, Multilayer Perceptron, Radial Basis Function Networks, Extreme Learning Machines, and Echo State Networks. The use of trainable ensembles led to a better performance. The use of robust tools is paramount to help governments in managing air pollution issues like hospital collapse during adverse air quality situations.

2 - Forecasting mobile sources risks using artificial neural networks

Thiago Antonini Alves, Hugo Valadares Siqueira, Tiago Emmanuel Nunes Braga, Deivdy Silva, Yago Honda, Yara Tadano

To implement public policies to reduce continuous emissions of green house gases (GEE) and other air pollutants are paramount. One of the main sources of GEE emissions are the use of fossil fuel. In this way, research related to emissions of pollutants from vehicles is paramount. Thus, seeking public policies encouraging the use and the development of more sustainable are essential to preserve populations' health. The World Health Organization estimates that 6.5 million premature deaths are related to air pollution. To better understand the health risks caused by emissions from mobile sources, is important to select the most important input variables. Therefore, this research aims to analyze and select the input variables that most affect the air pollution health risks. To do so, we applied three Artificial Neural Networks (Multilayer Perceptron, Extreme Learning Machines, and Echo State Neural Networks) to estimate the impacts of air pollution on outcomes for respiratory diseases (hospital admissions and mortality) using road vehicles fleet, distributed and sold fuels amount, and vehicle average mileage. The results showed that the best performance was achieved considering all the input variables. The ELM reached the best overall performance for hospital admissions, and ESN for mortality, both using deseasonalization methods.

3 - Simulator-based surrogate optimisation: an enhanced framework for surrogate modelling and optimisation

Yu Liu, Fabricio Oliveira

This work introduces a methodology for optimising complex functions common in high-fidelity simulations across engineering fields, emphasizing the strategic bridging of simulators and optimisation processes. Initially, we employ low-discrepancy sequence sampling to select simulation points, followed by training a surrogate model using a piecewise linear neural network with Rectified Linear Unit (ReLU) activation. Using Mixed Integer Programming (MIP), we reformulate the ReLU neural network as a MIP optimisation problem and solve it to find an optimal parameterisation of the simulator's input. Based on the best solutions obtained, we then enter an iterative domain-refined phase of resampling the simulator, retraining the surrogate model, and rebuilding and resolving the MIP problem. For resampling, we use an infill strategy that incorporates error assessment to balance exploration and exploitation. This process continues until the accuracy of the objective function reaches the desired tolerance, ensuring high surrogate accuracy near the optimum, with techniques like memory structure reuse and warm starts for efficiency. Validation against standard test functions indicates that refining the surrogate model via an error-informed resampling strategy significantly enhances optimisation efficiency. This framework advanced in surrogate-based optimisation by synergistically combining adaptive sampling, neural networks, and MIP for enhanced performance in complex simulations.

4 - Optimization with a multi-objective IRP model of the perishable supply chain for fast food restaurants, case of 3PL in Bogota D.C.

Javier Enrique Mantilla Rosas, Javier Arturo Orjuela Castro, Juan Pablo Orejuela Cabrera

The problem of perishable goods logistics in the fast food sector in the city of Bogota is the shortage and logistics costs of transportation routes for the supply chain carried out by logistics operators, there is a need to analyze the current situation to identify the variables that affect the current results and how to measure the IRP models (Programming, Multi-Objective) for the scheduling and routing of vehicles transporting perishables, in order to satisfy fast food customers (QSR - Quick Service Restaurant). Thus, the delivery of perishable food products (perishables) must have an adequate supply chain to avoid food waste, improve the performance of the agri-food supply chain logistics (AFSC) sector through different optimization models (LIRP, PIRP, IRP). In this research, a mathematical model IRP is defined where $G=(N,A)$, N is the set of vertices and A is the set of arcs, vertex 0 is the supplier, applying the optimization defined by Archetti

(2022) IRP (Inventory Routing Problem) whose objective function is to minimize the total inventory cost at the supplier, customers and transportation, where this problem is applied to the QSR sector in order to minimize nonconformities for the FFR (Fast Food Restaurant). The factual problem has 72 restaurants, with 3 multi-temperature products (Frozen, refrigerated and dry), the SLOAD+MCF model was chosen, which incorporates additional multi-product flow constraints with the ability to model the respective demands and capacities.

1 - An Efficient $O(n^2)$ Algorithm for Solving the Dynamic Matching Problem in TFT-LCD Cell Assembly Process

Shine-Der Lee, Peggy Lee

A polynomial time $O(n^2)$ algorithm for finding the optimum matching of panels to assemble TFT-LCD (Thin Film Transistor-Liquid Crystal Display) is presented in this talk. In the TFT-LCD cell assembly process, both TFT array and color filter (CF) substrate panels are pre-cut into several equal sized sub-panels. After the pre-cut, two sub-panels are matched to produce the final product, i.e., the LCD. We explore the special structure of a novel linear programming formulation, where the sub-panels are sorted by the number of good displays via lexicographic order, based on the location of good/bad displays on each sub-panel. Enhanced by these new properties, efficient solution procedures to find the optimum matching are developed for real time operation and sequencing in the assembly process. Computational experiments with several common pre-cut types and different batch sizes of panels have indicated that the solution procedures are efficient and effective.

2 - The change of Seidel energy of Turán graph due to edge deletion

Ayşe Dilek Maden, Şeyhmus Tarhan, Masood Ur Rehman

We consider any simple graph with finite vertex set and edge set. Turán graph is defined as the complete r -partite graph formed by partitioning its vertex set into r subsets, with vertex number as equal as possible, and joining two vertices by an edge if and only if they are located in different subsets. In his paper, Haemers defined the Seidel energy of a graph as the sum of the absolute values of all Seidel eigenvalues of this graph. Haemers noticed that the Seidel energy of any graph is invariant when the Seidel switching and complement of that graph are taken. Tian showed complete bipartite graph and the empty graph are switching equivalent. Thus Seidel energies of empty graph, complete graph and complete graph with same order are the minimum among all graph of same order. Tian proved that the Seidel energy increases when an edge is deleted in the tripartite Turán graph, and then gave the problem of whether this property would be hold for all Turán graphs. Liu and Chen, proved the above problem for quinate Turán graphs. We will show that the Seidel energy always increases when an edge is deleted for almost every Turán graphs. W.H. Haemers, Seidel switching and graph energy, MATCH Commun. Math. Comput. Chem., G.X. Tian, Y. Li, S.Y. Cui, The change of Seidel energy of tripartite Turán graph due to edge deletion, Linear Multilinear Algebra. Y.Y. Liu and X. Chen, The change of Seidel energy of quinate Turán graph due to edge deletion. Discrete Applied Mathematics.

3 - Resource-constrained network interdiction on nodes to mitigate threats

Orhan Karasakal, Ahmet Kabarcık

Network interdiction models have been utilized to analyze a wide variety of real-life problems such as military operations, illegal drug trafficking, increasing the preparedness of infrastructure against natural disasters or terrorist attacks, social networking, and preventing the spread of epidemics. This study explores a novel shortest-path interdiction problem variant with a single defense node against multiple adversarial nodes. The defense has limited resources to mitigate the threat posed by the adversary. By interdicting nodes and all connected arcs from those nodes, the defense aims to minimize the threat. The length of arcs connected to the interdicted node will increase inversely with the change in weight of the interdicted node. In this talk, the proposed mathematical model, the solution approach, and computational results will be presented.

4 - On a minimum-cost version of double Roman domination

Robert Manger, Ana Klobučar Barišić

Double Roman domination (DRD) is an optimization problem posed on an undirected graph. It is formally described as assigning weights to graph vertices according to certain rules. Informally, the problem can be interpreted as allocating some service providers (e.g., military formations) to chosen locations within a geographical area. Thereby the whole service (i.e., response to enemy attacks) should be established in a least expensive way, while still assuring a required "double Roman" level of robustness and reliability. The standard version of DRD treated in the literature identifies the total expense of service with the total number of needed providers.

In this work a new "minimum-cost" version of DRD is considered, which is more general and more realistic than the standard version. It assumes that the actual expenses of providing service can differ from one location to another. Thus, formally speaking, each vertex in our graph is given a cost that is interpreted as the cost of keeping one service provider at the corresponding location.

First, it is noted that the considered minimum-cost DRD problem is NP-hard, not only for general graphs but also for many special graph classes. Next, a dynamic programming algorithm is constructed, which shows that the problem can still be solved in linear time if the involved graph is a tree. Finally, as a solution for general graphs, a heuristic is proposed based on greedy approach and local search.

1 - Nonsmooth Optimization on Riemannian Manifolds in Manopt.jl

Ronny Bergmann

In many applications nonlinear data is measured, for example when considering rotations, bases of sub spaces or even sub spaces themselves. While this can be modelled as linear data with constraints, this induce more complicated algorithms. If the constraints on the other hand form a Riemannian manifold, for example the Special Orthogonal group, the Stiefel or the Grassmann manifold, one can employ classical unconstrained algorithms, while staying inherently feasible. In the recent years these algorithms were extended to non-smooth objectives as well as constrained optimization on manifolds.

In this talk, we present a framework and several algorithms that are available in Manopt.jl, which together with Manifolds.jl forms a family of Julia packages to efficiently solve optimization problems on Manifolds in Julia.

2 - goalp: Weighted and Lexicographic Goal Programming Interface for R

David Palma, Richard Hodgett

Goal programming (GP) is a special kind of linear programming (LP) technique where users seek to find a solution that deviates as little as possible from a set of goals, expressed as a series of linear equalities or inequalities. Applications include: planning manufacturing to match demand as closely as possible, given a limited number of raw materials; scheduling workers' shifts to match their stated availability as closely as possible; etc. Solving GP problems requires expanding the original goals into a larger LP problem. While the expansion is relatively straightforward, it is easy to make mistakes when utilising it manually in large problems. Furthermore, there are few software implementations of GP, with users mostly relying on general-purpose LP software. This makes solving large GP problems tedious and prone to errors. We fill this gap by introducing goalp, an R package for GP. It allows solving basic, weighted, and lexicographic GP problems, as well as a mixture of them. The package can take as input a human-readable representation of the goals, or a set of matrices. Then it automatically sets up the corresponding LP problem, which it later solves using the powerful lp_solve solver. goalp also allows mixing goals with traditional linear optimisation constraints, i.e. those not allowing for deviations. Furthermore, it allows for continuous, discrete, and dichotomous decision variables. goalp is currently available via CRAN, including a user guide (vignette).

3 - CasADi as the "bread and butter" in optimization for problem-solving engineers

Alejandro Astudillo, Joris Gillis

As an open-source software framework available in C++, Python and MATLAB since 2010, CasADi has been empowering academic and industrial researchers to rapidly prototype and efficiently solve challenging (dynamic) optimization problems.

Demonstrated through 3700+ citing papers, such optimization problems serve as an answer to many design, planning, estimation and control needs arising in engineering fields such as heat & energy, automotive, chemistry & pharmacy, or robotics.

The focus of this talk is on how CasADi facilitates vertical integration. The key facilitator is CasADi's versatile expression graph, capable of efficiently representing engineering specifications, dynamic models and transcription methods. A plugin system maps these expression graphs to the needs of a range of open-source and commercial optimization solvers, often including sparsity detection, (repeated) algorithmic differentiation, and linearity detection. By manipulating, communicating and code-generating the expression graphs, one can introduce solid software abstractions that pair readability and maintainability with excellent runtime performance. In particular, the talk presents the case of robot motion skill tool and follows the journey of the involved expression graphs all the way down to the CasADi solver plugins.

Ether achieved a major turning point by transitioning from the PoW (proof-of-work) consensus mechanism to PoS (proof-of-stake). This EIP (Ethereum Improvement Proposal) marked the dawn of a new epoch in blockchain innovation, enabling the emergence of creative applications with reduced transaction costs. Meanwhile, Ether experienced a price surge prior to deployment, followed by a subsequent deflationary trend. This paper investigates the impact of EIPs such as the Merge on crypto supply and demand, discussing whether these proposals function similarly to traditional monetary policies and analyzing the characteristics of EIPs that influence substantially. Furthermore, we discuss the broader implications of technology adoption and upgrades for Ether, investigating how technological uncertainty influences pricing and functional performance. Through an event study examining Ether's EIPs, we identify event-driven opportunities and risks, providing valuable insights for investors and protocol designers (i.e. policy makers) alike.

2 - Financial Risk Meter for The Romanian Stock Market

Alexandra Conda

This article aims to estimate the systemic risk of the Romanian stock market, using the FRM (Financial Risk Meter) methodology. This research contribution is about applying a novel systemic risk index to the Romanian financial system (FRM@RO), to identify potential sources of systemic risk, and to understand network interconnections, thus increasing risk awareness of both managers and regulators. By using data for companies listed at the Bucharest Stock Exchange (BSE), our article highlights several aspects of the systemic risk of the Romanian stock market. First, our study reveals that the main driver of systemic risk, especially during financial crises, is the volatility index, VIX. However, local factors, such as ROBOR interest rate and sectorial indices for financial investment companies, in general, and energy sector companies, in particular, are extremely important in triggering systemic risk. Second, the system risk indicator for the Romanian stock market, FRM@RO, may capture both investor sentiment, measured via the Google Trends Search Volume Index, and stock market volatility. Third, FRM@RO can act as an early warning indicator for economic turmoil, being able to predict periods of technical recession one quarter in advance. Fourth, by using network analysis, we can identify, daily, the level of market interconnectedness and highlight the main companies triggering tail co-movements.

3 - BitMood: Analyzing Bitcoin Trends through Facebook Emotions with AI

Daniel Traian Pele, Miruna Mazurencu Marinescu Pele, Stefan Gaman, Alexandra Conda, Raul Cristian Bag, Bogdan Paul Saftiuc

In the rapidly evolving landscape of cryptocurrency markets, the predictive power of social media sentiment has emerged as a pivotal area of exploration. This study presents a comprehensive analysis aimed at uncovering the intricate relationship between public sentiment expressed on Facebook and the volatility of Bitcoin trading volumes. Leveraging an extensive dataset of 120,000 Facebook posts tagged with Bitcoin-related keywords, combined with granular financial data from CoinGecko, we employ a methodologically advanced approach integrating Long Short-Term Memory (LSTM) networks, sentiment analysis via FinBERT, and topic modeling techniques. The LSTM model's ability to capture temporal dependencies in data makes it particularly suited for the volatility inherent in cryptocurrency markets, providing a more accurate forecasting tool compared to traditional time-series models. The findings from our analysis reveal significant correlations between the sentiment derived from social media and the fluctuations in Bitcoin market trends. These correlations not only validate the hypothesis that social media sentiment can serve as an effective predictor of market movements but also underscore the efficacy of LSTM networks in enhancing the precision of volume predictions.

4 - Predicting Realized Volatility: Insights from EU Energy Listed Firms During Crises

Cosmin Octavian Cepoi, Daniel Traian Pele

In this study, we examine price volatility among energy companies listed on European capital markets during an energy crisis. Our objective is to explore how these firms navigate turbulent market conditions, offering insights into price fluctuation dynamics within the challenging energy sector landscape. 1 - Constructive approaches to the analysis and construction of optimization algorithms

Adrien Taylor

In this talk, I will provide a high-level overview of recent principled approaches for constructively analyzing and designing numerical optimization algorithms. The presentation will be example-based, as the main ingredients necessary for understanding the methodologies are already present in the analysis of base optimization schemes, such as gradient descent. Based on those examples, I will discuss how those techniques can be leveraged for constructing Lyapunov-based analyses and optimal convex optimization algorithms. The methodology can be accessed through easy-to-use open source packages (including PEPit: <https://github.com/PerformanceEstimation/PEPit>), allowing to use the framework without the modelling pain. This talk is based on joint works with great colleagues that I will introduce during the presentation.

2 - Automated tight Lyapunov analysis for first-order methods

Manu Upadhyaya, Sebastian Banert, Adrien Taylor, Pontus Giselsson

We present a methodology for establishing the existence of quadratic Lyapunov inequalities for a wide range of first-order methods used to solve convex optimization problems. In particular, we consider (i) classes of optimization problems of finite-sum form with (possibly strongly) convex and possibly smooth functional components, (ii) first-order methods that can be written as a linear system on state-space form in feedback interconnection with the subdifferentials of the functional components of the objective function, and (iii) quadratic Lyapunov inequalities that can be used to draw convergence conclusions. We present a necessary and sufficient condition for the existence of a quadratic Lyapunov inequality within a predefined class of Lyapunov inequalities, which amounts to solving a small-sized semidefinite program. We showcase our methodology on several first-order methods that fit the framework. Most notably, our methodology allows us to significantly extend the region of parameter choices that allow for duality gap convergence in the Chambolle-Pock method.

3 - Counter-examples in first-order optimization: a constructive approach

Aymeric Dieuleveut, Adrien Taylor, Baptiste Goujaud

While many approaches were developed for obtaining worst-case complexity bounds for first-order optimization methods in the last years, there remain theoretical gaps in cases where no such bound can be found. In such cases, it is often unclear whether no such bound exists (e.g., because the algorithm might fail to systematically converge) or simply if the current techniques do not allow finding them. In this work, we propose an approach to automate the search for cyclic trajectories generated by first-order methods. This provides a constructive approach to show that no appropriate complexity bound exists, thereby complementing approaches providing sufficient conditions for convergence.

4 - Provable non-accelerations of the heavy-ball method

Baptiste Goujaud, Adrien Taylor, Aymeric Dieuleveut

In this work, we show that the heavy-ball (HB) method provably does not reach an accelerated convergence rate on smooth strongly convex problems. More specifically, we show that for any condition number and any choice of algorithmic parameters, either the worst-case convergence rate of HB on the class of L -smooth and μ -strongly convex quadratic functions is not accelerated (that is, slower than $1 - O(\kappa)$), or there exists an L -smooth μ -strongly convex function and an initialization such that the method does not converge. To the best of our knowledge, this result closes a simple yet open question on one of the most used and iconic first-order optimization technique. Our approach builds on finding functions for which HB fails to converge and instead cycles over finitely many iterates. We analytically describe all parametrizations of HB that exhibit this cycling behavior on a particular cycle shape, whose choice is supported by a systematic and constructive approach to the study of cycling behaviors of first-order methods. We show the robustness of our results to perturbations of the cycle, and extend them to classes of functions that also satisfy higher-order regularity conditions.

1 - A robust satisficing multi-objective optimization approach for bike-sharing systems with heterogeneous user types

Qingxin Chen, Shoufeng Ma, Ning Zhu

Recently bike-sharing systems begin to employ diverse pricing and subscription policies to cater to the commuting needs of heterogeneous users. Frequent riders choose to purchase subscriptions to reduce their commuting costs if the system is easily accessible. To maintain a high market share, operators should improve their service level to retain a large number of subscribers. In addition, there is also a small proportion of general customers who use the system occasionally. These customers contribute to the operational profits, and providers need to fulfill as much customer demand as possible to ensure high profitability. Thus, maintaining the service level and obtaining profits are both important operational objectives in bike-sharing systems. However, jointly optimizing these objectives for the heterogeneous users in bike-sharing systems is challenging, especially when demand is highly uncertain. To address these issues, this study presents a robust satisficing optimization model that jointly optimizes the service level and profits in bike-sharing systems under demand uncertainty. To avoid over-conservation of solutions, side information like weather and weekend is integrated into the model to describe the relationship between demand and these exogenous factors. Extensive numerical experiments show that our model achieves higher robustness, lower violation probability and degree, and higher average-case out-of-sample performance than other benchmarks.

2 - A Robust Stochastic Approach to Edge Computing Service Network Design with Network Attacks Uncertainties

Jie Chen

The Internet of Vehicles (IoV) serves as a foundational infrastructure for intelligent transportation systems. For service providers in the IoV and edge computing sectors, the meticulous design of edge computing networks is pivotal for securing a competitive advantage through enhanced cost efficiency and superior service quality. We introduce a robust stochastic model designed to tackle the network design challenge for edge servers effectively. This model incorporates critical considerations, such as the strategic placement of edge servers, capacity planning, congestion mitigation, accounting for stochastic demand, and guarding against unpredictable cyberattacks. Our primary objective is optimizing the network configuration to minimize total costs, including setup, capacity acquisition, congestion management, and data transmission. To represent this multifaceted issue accurately, we employ an M/M/1 queuing framework for assessing congestion in steady-state scenarios and refine our approach with a mixed-integer second-order cone programming framework. To manage uncertainties associated with network attacks, we incorporate an uncertainty set based on Renyi divergence, allowing us to adjust the model's conservativeness by modifying the divergence order. Furthermore, we propose a novel two-layer Benders decomposition approach to efficiently navigate the computational complexities inherent in solving this problem.

3 - Towards efficient transportation systems - designing a transportation system under uncertainty

Robert Hlavatý, Helena Brozova

We intend to provide a different perspective on the class of optimisation problems that are related to transportation systems. As a transportation system, we understand a situation that involves locations, means of transport, subject of transportation and the question at hand is finding an optimal way of distribution over this system, and we specifically focus on such systems that can be represented and solved using mixed-integer linear programming (MILP). Instead of following the usual solution approach, we focus on optimising the very system structure rather than finding an optimal solution over a system with fixed parameters. For demonstration purposes, we assume - for its simplicity - the traditional transportation problem of Hitchcock and Koopmans with possibly multiple objectives. In addition, it is considered that the capacity levels of suppliers (or customers) are bounded by given maintenance costs that increase with the increasing capacity. Given the constrained budget, we propose an optimal (in the cost-minimising sense) transportation system design that respects all objectives. We realise that these costs may be subject to uncertainty and therefore propose the robust-optimal transportation system design. We combine the De Novo optimisation approach with Gamma-robust optimisation to demonstrate our methodology which can be extended to any other transportation problem representable by MILP.

1 - Robust approaches for the Kidney Exchange Problem

Matteo Petris, Claudia Archetti, Ivana Ljubic

In the Kidney Exchange Problem (KEP), kidney exchanges can be modelled in a directed weighted graph as circuits starting and ending in an incompatible pair or as paths starting at an altruistic donor. The weights on the arcs represent the medical benefit which is a measure of the quality of the transplantation. For medical reasons, circuits and paths are of limited length. The aim of the KEP is to determine a set of disjoint kidney exchanges of maximal medical benefit or maximal cardinality (all weights equal to one). In this work, we consider two types

of uncertainty in the KEP which stem from the estimation of the medical benefit (weights of the arcs) and from the failure of a transplantation (existence of an arc). Both uncertainties are modelled via uncertainty sets with constant budget. The robust approach entails finding the best KEP solution in the worst-case scenario within the uncertainty set. We modelled the robust counterpart by means of a max-min formulation which is defined on exponentially-many variables associated with the circuits and paths. We propose two exact approaches to solve it: one based on the result of Bertsimas and Sim and the other on a reformulation to a single-level problem. In both cases, the core algorithm is based on a Branch-Price-and-Cut approach where the exponentially-many variables are dynamically generated. The computational experiments prove the efficiency of our approach.

2 - Optimistic versus Pessimistic Discrete Robust Optimisation Approaches: Opportunities and Challenges

Nader Azizi

The objective of a discrete robust optimisation approach e.g., budget uncertainty (Bertsimas and Sim, 2003&2004) is to find a solution that optimises against all scenarios in which up "a" number of coefficients that maximally influence the objective vary. Therefore, a solution produced by such method is optimal when exactly "a" coefficients are subject to change and it is feasible for other cases. This view of robustness could be regarded as "pessimistic" robust optimisation approach as the value of the objective reflects the worst-case scenario for a given budget of uncertainty. Building upon the concept of pessimistic robust optimisation, in this research we present an approach that we call "optimistic" robust optimisation. For a given problem with uncertain data in the objective function, the optimistic robust optimisation approach aims to find a solution in which exactly "b" number of coefficients with "minimum" impact on the objective are subject to change. We present examples and discuss opportunities and challenges pertain to the use of such (optimistic)robust optimisation approach.

3 - Distributionally robust fixed interval scheduling with heterogenous machines and random delays

Monika Matoušková

We deal with operational fixed interval scheduling problem where start times are given and the actual finishing times can be influenced by random delays. We further consider heterogeneous case, i.e., multiple job and machine types. And we assume that the multivariate distribution of delays follows an Archimedean copula. We consider the highest worst-case probability that the schedule remains feasible, where given proportion of marginal distributions of delays are stressed. This problem has an interesting reformulation containing a commonly used risk measure. We implement a decomposition algorithm. A possible application is gate assignment problem where incoming flights have to be assigned to available gates of an airport. In this problem, heterogeneity is caused by the fact that different aircrafts might need to be assigned to different gates. Moreover, there can be proportion of flights where worse delays occur.

4 - Robust Markov decision processes under parametric transition distributions

Christopher Kirkbride, Ben Black, Trivikram Dokka

We consider a robust Markov decision process for which we assume that the true transition distribution can be uniquely specified by a parametric distribution. We enforce this by the construction of a parametric ambiguity set that ensures the worst-case distribution is from the same parametric family of distributions. To conduct robust value iteration, we formulate the Bellman update as a linear program by discretising the ambiguity set. This scales poorly with problem size and requires significant pre-computation. We develop two algorithms for solving the update. Firstly, a cutting surface algorithm that reduces the time to solve the linear program but still requires the pre-computation. Secondly, a projection-based bisection search algorithm that removes the need for discretisation and pre-computation. Using a multi-period Newsvendor problem as an example, we compare these methods with non-parametric phi-divergence based methods from the literature. We show that the projection-based algorithm completes robust value iteration significantly faster than the other parametric algorithms, and is faster than the phi-divergence equivalent.

Chair: Clemens Thielen

1 - Characterizations of supported efficiency

Fabian Chlumsky-Hartmann, Anita Schöbel

When given a multi-objective optimization problem, one usually aims to find efficient solutions. Yet, often this is hard. Solutions that are often easier to identify than efficient solutions are supported efficient solutions. Intuitively, the set of supported efficient solutions can be described as the set that contains all solutions to the weighted-sum scalarization for "reasonable" choices of weights. However, different authors work with different definitions of supported efficiency (and—if in the image space—supported nondominatedness, respectively).

We examine definitions found in the literature and show that there are in fact differences. We are able to categorize them into four layers with an implicit hierarchy: The characterization at the highest level being the most restrictive. Moreover, we show that these layers only coincide in special cases, such as discrete, linear or bi-objective problems, while counterexamples show that these characterizations are not equivalent for more general problems. We argue which characterizations are best suited to be used for different kinds of multi-objective optimization problems.

Last, we extend our results to concepts of extreme supported efficiency and extreme supported nondominatedness, respectively.

2 - What is the meaning of pessimistic Pareto front in multiobjective bilevel problems?

Carlos Henggeler Antunes, Maria João Alves

Bilevel optimization deals with decision problems in which two decision-makers, the leader and the follower, control different sets of variables and have their own objective functions subject to interdependent constraints. A lower-level optimization problem is embedded in an upper-level problem. When the lower-level problem has multiple objective functions, the leader should cope with the uncertainty related to the follower's reaction. The leader can adopt a more optimistic or more pessimistic stance regarding the follower's choice within his efficient region, which is restricted by the leader's choices. The leader may also have multiple objective functions. The concepts of optimism and pessimism are well established when the leader has a single objective function. However, this is not the case when there are multiple objective functions at both levels. Most approaches aim to calculate the optimistic Pareto frontier (efficient solutions for the leader, considering that the follower's choices are always the best for the leader). However, this approach is seldom realistic, and the definition of the pessimistic Pareto frontier may not be consensual. We propose a definition of pessimistic Pareto front for bilevel optimization problems with multiple objective functions at both levels, which is compared with the optimistic Pareto front. These new concepts are illustrated using examples, emphasizing the difficulties associated with the computation of those solutions.

3 - Harnessing the Power of Quantum Computing for Multiobjective Optimization Algorithms

Pascal Halffmann, Ivica Turkalj

Multiobjective optimization problems (MOPs) present unique challenges, characterized by optimizing several conflicting objectives simultaneously and the, often exponential, number of Pareto-optimal solutions. Classical approaches typically involve scalarization to single objective problems obtaining at most one Pareto-optimal solution per single objective problem. The advent of quantum computing (QC), with its properties like superposition and entanglement, opens new frontiers in addressing the complexity of MOPs. So far, application-oriented problems, like MOPs, have barely been touched by quantum

algorithms. In this research, we explore the application of QC to discrete MOPs, capitalizing on its inherent capabilities to process vast and complex search spaces. We investigate how existing quantum optimization algorithms can be adapted and extended to the multiobjective domain. Based on previous work, we focus on variational algorithms and Grover Adaptive search and augment these with scalarization techniques and bound sets, among others. To demonstrate the efficacy of our approach, we apply these QC algorithms to an unconstrained multiobjective combinatorial optimization problem. Our results showcase that, while the computational advantage over classical computing is currently tested, QC adds value when tackling conceptually hard problems. Furthermore, we are paving the way for the practical applicability of quantum computing in solving real-world optimization problems.

4 - Exact solution methods for the bi-objective p-median and p-dispersion problem

Andreas Klose

Given an undirected graph, the bi-objective p-median and p-dispersion problem is to select p vertices of the graph such that the weighted average distance of the graph's vertices to their nearest of the selected p vertices is minimized and the distance between any two of the p selected vertices is maximized. For computing the bi-objective problem's non-dominated set the " ϵ -constraint method" as well as the "hybrid weighted sum and ϵ -constraint method" seem to be suitable approaches. ϵ -constraints put on the dispersion objective may, however, be enforced in different ways. Additionally, also the remaining constraint system can be formulated quite differently. In this talk, we compare the performance of different implementations of the ϵ -constraint and hybrid method based on different model formulations and means to enforce the ϵ -constraint. It thereby seems that in particular the application of Benders' decomposition for solving the scalarized problems gives promising results.

1 - Parametric upper and lower bounds of linear variations of a linear problem's LHS

Bardhyl Miftari, Guillaume Derval, Quentin Louveaux, Damien Ernst

Assessing the impact of various hypotheses is a common task when working on models. In this paper, we focus on the linear parametric problem where we assess the impact of unknown constraints' coefficients on the final objective. These multiple coefficients can vary linearly within a known range. Traditionally, this task is tackled using heavy computation, i.e., recomputing the optimum several times for every value of the coefficients, using approximations or using non-generic approaches. For large linear problems, we argue that computing every value of the coefficients in the interval is too computationally heavy and does not provide any information about the overall behavior between the points.

As a new approach to the problem, we derive several upper and lower bounds that allow us to avoid recomputing the problem for numerous coefficient values, provide guarantees between the computed points, as it does not allow for outliers, and require a smaller number of optimizations. We discuss these bounds and provide an iterative algorithm that uses them to compute an approximation to the original function within

a given error threshold. We analyze the performance of the bounds on toy and real-world problems and demonstrate the effectiveness of the approach.

2 - A Combined Convex Formulation Replacing Hierarchical Extended Logit Model for Travel Demand Forecasting

Youngseo Kim, Damon Wischik, Soroosh Shafieezadeh Abadeh, Gioele Zardini, Samitha Samaranyake

The travel demand forecasting model plays a crucial role in evaluating large-scale infrastructure projects, such as the construction of new roads or transit lines. While combined modeling approaches have been explored as a solution to overcome the problem of input/output discrepancies in a sequential four-step modeling process, previous attempts at combined models have encountered challenges in real-world applications, primarily due to their limited behavioral richness or computational tractability. In this study, we propose a novel convex programming approach and present a key theorem demonstrating that the produced optimal solution coincides with the one arising from the hierarchical extended logit model. This model is specifically designed to capture correlations existing in travelers' choices, including similarities among transport modes and route overlaps. The convex property of our model ensures the existence of solutions and naturally offers computational efficiency. The advantages of our proposed model are twofold. First, it provides a single unifying rationale (i.e., utility/entropy maximization) that is valid across all steps. Second, its combined nature allows one to systematically handle observed data, enabling a better representation of reality. Our convex programming approach shows promise in enhancing the accuracy and applicability of travel demand forecasting, thereby aiding in the decision-making processes for infrastructure projects.

3 - On the convergence rate of the difference-of-convex algorithm (DCA)

Hadi Abbaszadehpeivasti

In this talk, I present the non-asymptotic convergence rate of the DCA (difference-of-convex algorithm), also known as the convex-concave procedure, with two different termination criteria that are suitable for smooth and non-smooth decompositions, respectively. The DCA is a popular algorithm for difference-of-convex (DC) problems and known to converge to a stationary point of the objective under some assumptions. I derive a worst-case convergence rate of $O(1/\sqrt{N})$ after N iterations of the objective gradient norm for certain classes of DC problems, without assuming strong convexity in the DC decomposition and give an example which shows the convergence rate is exact. I also provide a new convergence rate of $O(1/N)$ for the DCA with the second termination criterion. Moreover, I present a new linear convergence rate result for the DCA under the assumption of the Polyak-Łojasiewicz inequality. The novel aspect of this analysis is that it employs semidefinite programming performance estimation.

4 - Modified Simplex Algorithm to Efficiently Explore Near-Optimal Spaces

Christoph Funke, Linda Brodnicke, Francesco Lombardi, Giovanni Sansavini

Modeling to generate alternatives (MGA) is an increasingly popular method in energy system optimization. MGA explores the near-optimal space (NOS), namely, system alternatives whose costs are within a certain fraction of the globally optimal cost. These alternatives may be preferred by real-world stakeholders due to intangible factors. Widespread MGA adoption is hampered by its additional computational burden. Current MGA methods identify boundary points of the NOS through repeated, independent optimization problems. Hundreds of model runs are usually required, and such individual runs are often inefficient because they repeat calculations or retrace previous trajectories. In this presentation, we introduce a novel algorithm, called Funplex, which uses elements from multi-objective Simplex to optimize many MGA objectives with minimal computational redundancy. On a simple linear program energy hub case study, Funplex is ten times faster than existing methods and yields higher-quality NOSs. Sensitivity analyses suggest that Funplex scales well with the number of

investment variables, making it promising for capacity planning models. The current implementation uses a full multi-objective tableau and therefore requires high memory and has poor stability on large models. Nonetheless, Funplex is a proof-of-concept that demonstrates the untapped potential of new solver methods. Further research on the topic may make MGA more standard and accessible among modeling teams.

1 - Efficient Approximations for American Options in Markets with Daily Price Limits

Jia-Hau Guo, Yi-He Chang

This paper proposes solutions for pricing American options on stocks in markets with daily price limits. We first extend the intraday density function of Guo and Chang (2020) to a multi-day one. Next, we adopt the fast Fourier transform (FFT) to derive accurate and efficient formulae for American options in the framework of Kim (1990) and Chang et al. (2016) and, further, employ the three-point Richardson extrapolation to accelerate the computation. Finally, the accuracy of our proposed methods is verified by simulations. We also note that more restrictive daily price limits could force put options to be exercised earlier.

2 - A new method to solve Volterra integral equations for variable annuities evaluation with stochastic volatility

Immacolata Oliva, Roberto De Marchis, Antonio Luciano Martire

A Variable Annuity (VA) differs from traditional life insurance products because, when the insurer invests the policy premium in a risky portfolio, the policyholder bears profits or losses according to the investment performances. In general, the dynamics of such a portfolio are defined via a geometric Brownian motion with constant interest rate and volatility, see e.g. Shen et al. (2016) and De Angelis et al. (2022). However, such a choice might be unrealistic, since it fails to incorporate well-known stylized facts observed in the financial market, such as the volatility smile/skew, see e.g. Heston (1993). Moreover, the presence of an American option embedded in the structure of a VA makes it unfeasible to determine a closed-form formula for such a contract, regardless of the market model. Therefore, we have to resort to ad-hoc numerical techniques, such as finite difference methods for the associated PDE, see e.g. Shen et al. (2016). Another possible route is to refer to the integral equation characterizing the early exercise boundary, as shown in Kim (1990). Within the latter setting, and along the lines of Adolfsson et al. (2013), in this paper, we propose a novel algorithm to solve integral non-linear two-dimensional Volterra equations in a stochastic volatility framework by exploiting specific features of the involved Fourier-type integrals.

3 - Stochastic Ito-Volterra integral equations arising in finance: a streamlined numerical approach

Antonio Luciano Martire, Immacolata Oliva

In recent years, stochastic integral equations of Volterra type have been employed as modelling tools for financial, economic, and demographic problems. In such a perspective, it is well known that a nonlinear stochastic Ito-Volterra integral equation is well-known model widely used simulating stock and electricity prices. Unfortunately, these kinds of equations do not allow closed-form solutions, but require the use of numerical methods to obtain suitable approximations. In this paper, we present a feasible, fast, and accurate numerical algorithm to evaluate the unknown solution of such equations. We mainly exploit the

Lipschitz condition, which needs to be assumed in order to ensure the existence and uniqueness of the solution of this kind of equations, and a particular version of the mean value theorem for stochastic integrals. We also provide an extensive convergence analysis for our proposal.

1 - Accounting for heuristics in reputation systems. An interdisciplinary approach in aggregation processes

René Fahr, Dirk van Straaten, Vitalik Melnikov, Eyke Hüllermeier, Behnud Mir Djawadi

Product ratings help customers to evaluate the quality of a product prior to their purchasing decision in online markets. To overcome information overload, the vast amount of reviews is aggregated to a single scalar value, typically the arithmetic mean. However, customers may not base their purchasing decision on the arithmetic mean but on other aggregation functions such as the amount of 1-star and/or 5-star ratings. Our research question therefore asks to what extent the arithmetic mean really reflects how customers aggregate product ratings. In our incentivized laboratory experiment, participants are shown bundles of different products, and subsequently, asked to rank them according to their preferences. Analyzing the rank data with a Plackett-Luce model, we find that the arithmetic mean indeed best explains the obtained data. However, our analysis on an individual level reveals more heterogeneous aggregation patterns. In particular, a significant share of participants exhibits a binary bias. That is, moderate 2-star and 4-star categories get over- and the extreme 1-star and 5-star categories under-weighted. We also observe minor clusters who prefer products which have the lowest amount of 1-star ratings. The way our participants aggregate the ratings is neither affected by variation of provided information nor by individual characteristics such as experience, risk attitudes, or demographics.

2 - Data-scarce identification of game dynamics via sum-of-squares optimization

Antonios Varvitsiotis

Understanding how players adjust their strategies in games, based on past experience, is a crucial tool for policymakers. It enables them to forecast the system's eventual behavior, exert control over the system, and evaluate counterfactual scenarios. The task becomes increasingly difficult when only a limited number of observations are available or difficult to acquire. In this work, we introduce the Side-Information Assisted Regression (SIAR) framework, designed to identify game dynamics in multi-player normal-form games only using data from a short run of a single system trajectory. To enhance system recovery in the face of scarce data, we integrate side-information constraints into SIAR, which restrict the set of feasible solutions to those satisfying game-theoretic properties and common assumptions around strategic interactions. SIAR is solved using sum-of-squares optimization, resulting in a hierarchy of approximations that provably converge to the true dynamics of the system. We showcase that the SIAR framework accurately predicts player behavior across a spectrum of normal-form games, widely-known families of game dynamics, and strong benchmarks, even if the unknown system is chaotic.

3 - Sequential sponsored-products and off-amazon advertising optimization for retailers

Yina Ning, Yangyang Xie, Houmin Yan

The Sponsored-Products (SP) advertisement is a popular way for promoting products on Amazon. Retailers can choose and pay for specific keywords to secure ad placements for their products. These keywords are the ones that shoppers are likely to search for when looking for products on Amazon. To improve the efficiency of SP ads, retailers who have a large catalog of products often create ad groups for products with similar attributes. An ad group consists of a set of products and a set of keywords, and all the products in the ad group share the same keywords set. Retailers may also choose to link to external websites for advertising their products and attracting consumers, which is called off-Amazon (OA) ads. This study focuses on the sequential SP and OA ads optimization problem for retailers. Practically, many retailers set sales targets for products as manufacturing and logistics are planned ahead of time. Hence, we consider that the objective of the retailer is to minimize the expected long-run average cost associated with advertising and the cumulative deviation between the sales target and actual sales. When the mean of the sales number per unit time (i.e., sales rate) for each product is known, we characterize the optimal sequential Sponsored-Products and off-Amazon advertising policy (abbreviated as SSPOA policy) for products in an ad group, which is of a threshold type. However, in reality, retailers may not know the exact mean of sales rates, and therefore the SSPOA problem

4 - A Solomonic Approach to Core Allocations For Big Boss Games

Ismail Özcan, Ana Meca

In this study, a new core allocation formula using the tau-value and Shapley-value for the big boss games class has been proposed, referred to as the weight function, and a generalization has been provided. The tau-value consistently belongs to the core, whereas the Shapley value may not be part of the core in the big boss game class. While the tau-value might favor the big boss, it might not meet the expectations of other players. Conversely, the Shapley-value could satisfy other players but might not suffice for the big boss. To resolve this dilemma, we proposed a new core allocation family and a Solomonic solution procedure for the big boss games class.

1 - Extended convergence analysis of the Scholtes-type regularization for cardinality-constrained optimization problems

Sebastian Lämmel, Vladimir Shikhman

We extend the convergence analysis of the Scholtes-type regularization method for cardinality-constrained optimization problems. Its behavior is clarified in the vicinity of saddle points, and not just of minimizers as it has been done in the literature before. This becomes possible by using as an intermediate step the recently introduced regularized continuous reformulation of a cardinality-constrained optimization problem. We show that the Scholtes-type regularization method is well-defined locally around a nondegenerate T-stationary point of this regularized continuous reformulation. Moreover, the nondegenerate Karush-Kuhn-Tucker points of the corresponding Scholtes-type regularization converge to a T-stationary point having the same index, i.e. its topological type persists. As consequence, we conclude that the global structure of the Scholtes-type regularization essentially coincides with that of CCOP.

2 - Discontinuous Nash Equilibria in a Two-Stage Linear-Quadratic Dynamic Game With Linear Constraints

Rajani Singh, Agnieszka Wiszniewska-Matyskiel

In this work, we study a simple example of a two-stage linear-quadratic dynamic game in which the presence of simple linear state dependent constraints results in nonexistence of continuous symmetric feedback Nash equilibria and the existence of continuum of discontinuous symmetric feedback Nash equilibria. The example is not an abstract model—it has obvious applications in economics of resource extraction.

3 - On vector optimization problems

1 - Seismic optimizing inversion with multi-head attention mechanism and transformer

Yanfei Wang

The technology of reflection coefficient inversion aims to broaden the spectrum and increase the dominant frequency based on the effective collection of data. Reflection coefficient inversion can be achieved through conventional physics-based optimization modeling. In recent years, machine learning has seen tremendous development in the field of inverse problems. Deep learning has made breakthrough progress in fields such as image processing and natural language processing (NLP). Following the convolutional neural network (CNN) and recurrent neural network (RNN), the transformer network architecture, comprised only of self-attention mechanisms and feedforward neural networks, has also become a research hotspot in recent years. Our latest work has realized blind seismic reflection coefficient inversion using a transformer network. By setting up appropriate encoders and decoders and incorporating physical mechanism constraints, the transformer has demonstrated powerful seismic inversion capabilities. Experimental data indicates that the new method based on the transformer network architecture does not require any a priori assumptions about the seismic records' reflection coefficient series, seismic wavelets, or Q value models; it possesses strong noise resistance and resolution; after the model training is completed, it has relatively good generalization performance, and the model prediction process is more efficient compared to traditional methods.

2 - A New Derivative-free Method Using an Improved Under-determined Quadratic Interpolation Model

Ya-xiang Yuan

In this talk, we give a new derivative-free method by introducing an improved under-determined quadratic interpolation model. We analyze the least norm type under-determined quadratic interpolation model proposed by Conn and Toint from the perspective of the property of trust-region iteration. We found the Karush-Kuhn-Tucker multiplier's non-determinacy when constructing a quadratic model considering the trust-region iteration in the case where the current iteration

point is on the boundary of the trust region. The lack of the quadratic model's uniqueness caused by the Karush-Kuhn-Tucker multiplier's non-determinacy leads us to propose a new model by selectively treating the last obtained under-determined quadratic model as a quadratic model or a linear one. We propose the theoretical motivation, computational details, and the quadratic model's formula derived from the Karush-Kuhn-Tucker conditions. The formula is implementation-friendly for the existing model-based derivative-free methods. The numerical results with released codes support the advantages of our quadratic model in the derivative-free optimization methods. To the best of our knowledge, this is the first work considering the property of trust-region iteration and the model's optimality when constructing the under-determined quadratic model for derivative-free trust-region methods.

3 - Single-loop primal dual method for complex-field phase optimization problem in wireless communication

Cong Sun

Abstract: Reconfigurable intelligent surface (RIS) is a hot candidate technology for 6G. RIS aided multiple input multiple output interference channel is considered. The precoding beamforming matrices and RIS parameters are jointly designed for sum rate maximization. The approximation explores the upper bound of the sum rate, and the optimization problem is reformulated as a minimax saddle point problem through the approximated Lagrangian function. The single-loop primal dual method is designed for the saddle point problem, where the primal variable is updated through one projected gradient step and the dual variable is solved through quadratic interpolation. It turns out that the proposed method performs well numerically, which achieves promising sum rate with very little computational cost.

Recent advances on Variational Inequalities and Equilibrium Problems II

Stream: Variational Inequalities and Equilibrium Problems: From Theoretical Advances to Real World Applications
Invited session

Chair: Mauro Passacantando

1 - Robust Generalized Nash Equilibria

Sara Mattia, Mauro Passacantando

Robust optimization is an established technique for handling data uncertainty in optimization problems. However, most of the results refers to problems with a single decision maker, whereas less results are available for frameworks that include multiple decision makers. These settings are very common in several applied contexts, where different stakeholders may be involved in the decision making problem, with various roles and decision power. This is the case for example, for problems arising in healthcare, urban planning or shift scheduling problems. The present study aims at generalizing the results that are known for robust optimization problems with a single decision maker to non-cooperative games, where multiple decision makers (players) are present. In particular, we focus on the Generalized Nash Equilibrium Problem (GNEP), where both the objective function and the feasible region of each player are affected by the actions of the other players. The robust version of a GNEP with uncertain parameters is defined and its continuity, differentiability, convexity and monotonicity properties are investigated. Moreover, an existence result of robust equilibria is given. In the case of linear or quadratic dependence of the objective functions and constraints on the uncertain parameters, equivalent reformulations of the robust GNEP are provided.

2 - Complementarity problem formulation of Fujita-Ogawa model with heterogeneous players

Shunsuke Hayashi

In this study, we focus on Fujita-Ogawa (FO) model, which is known to be one of equilibrium models to analyze the agglomeration patterns of cities. FO model has a scheme of population game, in which the numbers of firms and households for each location serve as variables, and their distance-decay interactive benefits and commuting costs serve as payoffs. In this study, we assume the heterogeneous attribute for each firm, and formulate its equilibrium by means of complementary conditions. We also calculate some equilibrium solutions in a graphical manner.

3 - Recent Advances on the Variational Inequality approach to Network Games

Fabio Raciti

Recent Advances on the Variational Inequality approach to Network Games

Network Games, (NG), are a class of games where each individual (player) is identified with a node of a graph and the players that can interact directly are connected through links of the graph. The specificity of these games is the central role played by the graph structure in the description of the patterns of interactions, and in the final social or economic outcome. The mathematical consequence of this description is that some interesting results depend on quantities such as the spectral radius of the adjacency matrix, its minimum eigenvalue, and its powers. The theory of Variational Inequalities has not yet been exploited in the context of NG, with only a few exceptions. In this talk we outline some recent results as well as some research perspectives within this framework.

MCDA and Composite Indicators: Issues, Advances and Applications 1

Stream: Multiple Criteria Decision Analysis
Invited session

Chair: *Menelaos Tasiou*

Chair: *Panagiotis Ravanos*

1 - Deck of Cards method for Hierarchical, Robust and Stochastic Ordinal Regression

Silvano Zappalà, Salvatore Corrente, Salvatore Greco

In this paper, we present how to apply the Deck of Cards Method (DCM) for ordinal regression. While the DCM is very well-known and applied in Multiple Criteria Decision Aiding, here, we apply it to assign a value to each alternative evaluated on a set of criteria hierarchically structured. The Decision Maker can provide precise or imprecise information at different levels of the hierarchy of criteria using the classical DCM framework. This information is therefore used to infer a value function compatible with it. The compatible value function can be a simple weighted sum, a piecewise linear value function, a general monotonic value function, or a Choquet integral. To provide robust recommendations to the Decision Maker, the Robust Ordinal Regression and the Stochastic Multicriteria Acceptability Analysis are applied. Even if in different ways, both of them take into account the whole set of models compatible with the preference information provided by the Decision Maker. The applicability of the new proposal is shown by an example in which Italian regions are evaluated on criteria belonging to Circular Economy, Innovation Driven and Specialization macro-criteria.

2 - Restricting Weight Shares in the Benefit-of-the-Doubt Model

Panagiotis Ravanos, Giulio Caperna, Giannis Karagiannis

In the construction of composite indicators by the Benefit-of-the-Doubt (BoD) model, proportional virtual weight restrictions (pie-shares) are frequently used to place bounds on the normalised indicators' relative contribution to the composite for each assessed entity, based either on expert views or simply to prevent the occurrence of zero indicator weights. Two important issues associated with pie-share restrictions are that they cannot accommodate zero values for individual indicators and that they result in evaluating each assessed entity based on a different best-practice frontier, which makes the resulting BoD scores incomparable across entities. In this paper, we introduce a novel type of weight-share restrictions in the BoD model, which involve placing bounds on the share of each normalised indicator's weight to the sum of indicator weights rather than the product of an indicator and its weight, which is the case with pie-share restrictions. We show that weight share restrictions can accommodate zero values for individual indicators and that they result in evaluating all entities based on a common best-practice frontier, enabling the ranking of entities based on their BoD scores. We also discuss how, due to the nature of the BoD model, weight-share restrictions are the proper and most intuitive way to place an absolute bound on an indicator's weight, and we illustrate our findings using data from the European Commission's Cultural and Creative Cities Monitor.

3 - Assessing the Sustainability of European Countries Using Quantitative Techniques

Sandra González Gallardo, Ana Belen Ruiz, Francisco Ruiz, Mariano Luque, Pedro Fernandez-Rodero

In this work, we study the sustainability performance of European Countries by applying a methodology that combines both multiple criteria decision-making and statistical techniques. Using individual sustainability development indicators for the European countries available in the EUROSTAT database, we first build composite indicators to assess the economic, social, and environmental dimensions of the territories. Based on the information obtained, secondly, a statistical analysis is done to regress the composite indicators only considering those individual indicators that are somehow controllable by policy makers. The main objective is to get some insights into the impact that a modification of these controllable individual indicators would have on the overall sustainable development. Finally, we focus on the Spanish case, whose sustainability situation can be improved, as this country does not reach the best possible values of the composite indicators of the three dimensions. However, to make a decision about how to improve its situation, further information is needed in order to know the extent of the possible improvement, the trade-offs existing among the dimensions, and how this improvement could be attained. Therefore, we build a multiobjective optimization problem based on the statistical analysis previously performed, which is aimed at identifying the most desired compromise among the three sustainability dimensions to enhance the sustainability situation of Spain.

4 - A Composite Indicator for Analysing the Entrepreneurship Environment in Europe: A Goal Programming Approach

Rui Fragoso, António Xavier

The Global Entrepreneurship Monitor (GEM) report provides the results on entrepreneurship held every year across the world. The rising number of participating countries in GEM contribute to build the biggest database on entrepreneurship, which includes a variety of relevant primary information on different aspects of entrepreneurship. This database allows to obtain insights on the patterns and trends that prevail in the participating economies, from two perspectives: geographic regions and economic development stages. Integrating the GEM, the National Experts' Survey (NES) provides insights from experts in each economy on nine Entrepreneurial Framework Conditions (EFC) considering a set of 12 indicators. These indicators provide relevant information regarding the entrepreneurial environment of each country. According to the best of our knowledge, in the literature, there is not any tool that allows analysing this information, in a simplified way

and establishing rankings. In that scope, a composite indicator may be a useful tool for policy making, providing information on countries performance, conceptualizing phenomena and simplifying complex information. Also, when defining rankings, several goals must be considered and the fact each indicator doesn't have the same importance for the entrepreneurial environment. In this context, the European Union countries is a relevant study area for the diversity of countries with specific entrepreneurial policies and environment

Simulation and Modelling for Decision Support

Stream: Decision Support Systems

Invited session

Chair: Femi Olan

Chair: Shaofeng Liu

1 - Handling Issues of Uncertainty while designing DSS

Gil Greenstein

This Research deals with various principles that were examined and identified during Decision-Making processes and integrate them to a comprehensive methodology for modeling an analytical model which instructs how to design a DSS properly. The analysis allows explaining a decision maker's behavior under the assumptions of bounded rationality, over time and it leads to a better understanding of the performances of DSS during their life-cycle. The model deals with the following principles: The resolution of Information - The analysis demonstrates the trade-off between accuracy of information and time and costs re-sources to gain this information. The timing of decision-making - the analysis shows how to support decision makers (e.g.: politicians) to take their decisions in the right moment. A model will be under the assumption that information resources become more accurate over time, but opportunities sometimes vanish over time. Bounded Rationality of decision-makers - it is assumed that decision makers could not adopt a new set of decision rules and it takes to know how to handle with a new DSS platform. The analytic model will clarify how to consider this issue during a design process of DSS. Multi Criteria approach - the analysis deals with decision situation where it is assumed that a decision-maker cannot formulate a joint utility function constituted from different criteria which are completely inestimable or estimable partly.

2 - Rethinking Durable Solutions: A System Dynamics Approach for Enhanced Decision-Making in Displacement Contexts

Patience Saungweme, Stefan Spinler

Escalating human displacement resulting from conflict, natural disasters, and climate change, termed complex crises, represents a major global challenge today. Refugees, the second-largest displaced group, situated in locations experiencing protracted crises with declining living conditions, represent a major hurdle for humanitarian efforts. There exists low interest in research on Humanitarian Operations on the overlap of Humanitarian Logistics and Political Science, essential for addressing issues in conflict-induced displacement interventions. This area lacks exploration of viable operations management strategies in conflict zones, beyond access and security, for durable solutions realization. Decisions regarding refugees are subject to the political discretion of host countries, influenced by foreign policy negotiations and minimum standards set by the United Nations High Commissioner for Refugees for basic survival needs. This often neglects long-term welfare needs of food security and livelihood recovery. We aim to create a framework using System Dynamics to analyze trade-offs between temporary and permanent solutions in crises causing displacement, incorporating protractedness and conflict sensitivity. The

result expected is a codification of realities and insights gained from multiple case analysis, and their inclusion into a versatile operational decision framework for various displacement contexts and future integration with traditional Operations Research models.

3 - Simulation-based scenarios for optimizing resource planning in warehouse operations: A practical approach

Dimitrios Zormpas, Vasileios Zeimpekis

Resources in warehouses include both workforce and material handling equipment and still remain a persistent challenge in warehouse planning operations. Since the productivity of any warehouse process increases with the speed at which the products are moved within the storage facility, optimizing resource planning is crucial for improving productivity and minimizing operational cost. An approach for optimizing resources is via simulation modelling. Indeed, Discrete-event simulation (DES) is one of the popular modeling techniques which has been used for warehouse process and resource optimization. To this end, this article, presents multiple simulation models with the aim to identify the optimal resources (i.e. workforce, docking stations, material handling equipment) needed for receiving, put-away, picking, packing and dispatching processes in a given case study with the aim to complete all processes in certain time horizon. For each process, various scenarios are developed that evaluate the impact of adopting different planning strategies. The models developed identify the mix of workforce and equipment that provide the best process completion time. The results are encouraging, showing that the use of simulation models may identify the selection of the best workforce-equipment mix and subsequently improve warehouse operations.

Which Solver?

Stream: Making an Impact

Invited session

Chair: Johan Kellerth Fredlund

1 - MIP Solvers In Practice

Making An Impact, Tobias Achterberg, Frédéric Gardi, Timo Berthold, Rubén Ruiz, Andreas Westerlund

Practitioners who use MIP have a great choice of possible softwares. The huge choice can make it harder to make decisions; and that's where this 90' session should be invaluable. We bring together representatives from Xpress, Gurobi and Hexaly, with two heavy users of one or more of these we try to answer questions like: Why use a 3rd party solver instead of in house options? What problems have companies experienced in this approach? And of course... which solver is the best in practice? There will be plenty of opportunity for audience Q&A. This is a reprise of a session first held in 2018. Since then, the landscape and the power of solvers has changed immeasurably, and we will be reviewing just how users can make the most of this. For full details of speakers, please see the 'Making an Impact' page on the main conference website.

■ WC-47

MCDA in medicine

Stream: Multiple Criteria Decision Analysis

Invited session

Chair: Yorgos Goletsis

1 - MCDA for Health Technology Assessment: Trends and Challenges

Yorgos Goletsis, Garoufalia Naka, Kostas Athanasakis, Michalis Doumplos

Priority setting in healthcare's financing is a multidimensional problem as there are conflicts among different stakeholders' groups (patients, scientific specialists, healthcare providers, manufacturers, insurers). Allocating the limited resources and funding to (new) medical technology requires an evaluation of the multiple types of value medical technology (i.e. tools, tests, devices, drugs, vaccines, processes, etc.) can occur, which extend the traditional economic evaluation which is often limited to the evaluation of costs and a single health related outcome (such as QALYs, DALYs, etc.).

Multicriteria Decision Analysis (MCDA) can expand the current more or less standard assessment process by introducing multiple (and often conflicting criteria), the preferences of multiple stakeholders, including the society.

For this reason, in our paper we are reviewing the relevant literature and through a detailed review and bibliometric analysis of 226 papers we identify the theoretical foundations and trends in the relevant literature. Despite the relevant progress over the last years, MCDA for Health Technology Assessment needs to address several challenges before being widespread. Such challenges could be conceptual, methodological or organizational. Overcoming these challenges can help embedding the multicriteria concepts and methods in healthcare technology evaluations and decision making.

2 - Comparison of HB Shrinkable Estimators and DCE Simulators for Demand for Care

Christine C Huttin

OBJECTIVES: this communication aims to discuss how and in which context a random price generator for health care markets can be useful in comparison with other approaches for economic modeling and pricing of medical products and services **METHODS:** a comparison of the different approaches used will be discussed with their statistical limitations: nested logit models, cumulative logit models, latent model of choices, shrinkable estimators with Hierarchical Bayesian approach, combination of robust pricing optimization with multinomial logit choice models, and choice models with random price generators and current model application of the BLP model on NGS sequencing. **RESULTS:** random generators proved to be useful but do not fit any kind of structural conditions to adjust supply and demand of health re markets in more or less regulated health and economic systems. an approach by sets of alternatives and choice models allow to adjust for heterogeneity of demand but lack of price data in some markets make it useful to rely on shrinkable estimators with HB approaches. In duopoly cases, the use of BLP is currently tested and may help for investigation of antitrust policies. **CONCLUSIONS:** the complexity of health care markets lead to consider various combinations of models and even participatory modeling to reach growing consensus with various layers of decision makers both on the payer side and the economic actors switching to data driven models for both drug and vaccines.

3 - Integrating Multi-Criteria Decision-Making (MCDM) in Traditional Chinese Medicine (TCM) Diagnosis: A Case Study on Post COVID-19 Syndromes

Mei-Chen Lo, Fang-Pey Chen, Yen-Ying Kung

This research delves into the synergistic application of Multi-Criteria Decision-Making (MCDM) methodologies in Traditional Chinese Medicine (TCM) diagnosis, with a specific focus on Post COVID-19 Syndrome. The global aftermath of the pandemic has heightened the demand for nuanced diagnostic approaches, and this study aims to bridge the gap between traditional diagnostic principles and modern decision-making tools. Through a detailed exploration of MCDM techniques such as Analytical Hierarchy Process (AHP) and Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), the research integrates these methodologies into the TCM diagnostic framework. The case study on Post COVID-19 Syndrome serves as a

practical application, examining how MCDM enhances diagnostic precision and effectiveness. The findings not only contribute to the evolution of TCM practices but also hold implications for a more integrated and responsive healthcare approach in the post-pandemic era.

DEA methodological developments I

Stream: Data Envelopment Analysis and its Application
Invited session

Chair: *Mehdi Toloo*

1 - Complete Ranking and Benchmarking Methods for Improved Efficiency Assessment in Neutrosophic Environments

Deena Sunil, Kshitish Kumar Mohanta, Vishal Chaubey, Poornima Hulipalled

The measurement of the relative efficiency of the Decision-Making Units (DMUs) in a fuzzy environment is conducted through the employment of the fuzzy data envelopment analysis (FDEA). In FDEA, one of the primary concerns is to identify the benchmarking for inefficient DMUs, in order to enhance the efficiency of these particular units. Additionally, the complete ranking of the DMUs is also an important aspect to consider within the realm of FDEA. To address these issues, this article proposes the utilization of a reference set and complete ranking technique for the DMUs in a neutrosophic environment, which is an extension of the fuzzy environment that effectively represents uncertainty. In order to evaluate the relative efficiency of the DMUs, the Neutrosophic DEA model is solved using the possibility mean approach. Furthermore, a reference set based on the possibility mean function is suggested to identify peers for the inefficient DMUs. Moreover, the Neutrosophic super efficiency model, is employed to assess the relative super efficiency score of the DMUs. This super efficiency score is then utilized to achieve a complete ranking of the DMUs. To demonstrate the effectiveness and applicability of the proposed approach, a numerical example is considered.

2 - Adding counterfactual interpretation to DEA

Gordana Savic, Ognjen Nikolić, Sandro Radovanović

This paper investigates the integration of the Synthetic Control Method (SCM), a proven method to analyze an impact of policy interventions, and Data Envelopment Analysis (DEA), a well-known mathematical technique for measuring relative efficiency of decision-making units with multiple inputs and multiple outputs, to evaluate the effect of policy interventions on the efficiency of decision-making unit. Specifically, this paper applies these methodologies to assess the efficiency of Serbian banks over a given period, focusing on the influence of a merger between two principal banks on their operational performance, and answering a counterfactual question whether efficiency of a bank would be the same if a merger did not happen. The study demonstrates that SCM can be an effective tool for analyzing the repercussions of policy measures on decision-making unit efficiency. In other words, we suggest combining these two methods in the future, in order to conclude whether an intervention really has an impact on efficiency.

3 - Embracing fairness within a cross-efficiency hierarchical network DEA system

Marios Kremantzis, Siwei Xiao, Leonidas Sotirios Kyrgiakos, George Vlontzos

Several scholars have utilized hierarchical network Data Envelopment Analysis modeling techniques to assess the performance of complex structures. However, there has been limited consideration given to the integration of a peer-appraisal setting within a self-evaluation hierarchical context. This aims to enhance discriminatory power and mitigate the issue of unrealistic weighting scheme. To this end, our study

extends the single-stage hierarchical additive self-evaluation model of Kao (2015), by integrating the well-established cross-efficiency method. An original combination of a maxmin secondary goal model and the Criteria Importance Through Inter-criteria Correlation (CRITIC) method is proposed, to expand the basic hierarchical self-evaluation model. The maxmin model addresses the issue of the non-unique optimal multipliers obtained from the self-evaluation model, ensuring a more realistic weight scheme. The CRITIC method, that tackles the aggregation problem by objectively determining weights of criteria, rewards the minority and is conducive to a fairer evaluation. Results indicate that the proposed approach is more likely to obtain a unique efficiency and ranking score for the units under consideration. This study entails a numerical experimentation aimed at evaluating the efficiency of a set of 20 universities while validating the applicability of our proposed approach.

4 - Exploring Productivity Growth: A Data Envelopment Analysis in Single Input/Output Scenarios

Mehdi Toloo, Aliasghar Arabmaldar, Adel Hatamimarbini

The Malmquist Productivity Index (MPI), a major DEA advancement, evaluates productivity changes over time in decision-making unit (DMU) with multiple inputs and outputs. This paper addresses the underexplored scenario of a single input with multiple outputs or vice versa. Existing MPI models often overlook non-Archimedean epsilon, but our novel approach incorporates it in scenarios featuring a single input or output. An efficient procedure is proposed for problem-solving in both input- and output-oriented cases. Theoretical validation through theorems is complemented by a practical analysis of productivity growth across 18 OECD countries from 2005 to 2021, demonstrating the methodology's effectiveness.

■ WC-49

Wednesday, 12:30-14:00 - Room: M1 (building: 101)

Machine scheduling problems

Stream: Lot Sizing, Lot Scheduling and Production Planning

Invited session

Chair: Shudong Sun

1 - Job Scheduling by Choosing and Tiling Existing Scheduling Segments

Gavriel David Pinto, Inessa Ainbinder, Yehuda Hassin, Daniel Lifshitz, Uriel Israeli, Gad Rabinowitz

In a flexible job shop problem, a typical job consists of a set of operations with precedence relationships among them. Each operation may be performed in various modes, where each mode requires certain renewable resources, each for some specific time-period within the duration of the operation. We call the resources' timings for performing a specific operation in a specific mode a scheduling segments. We assume that scheduling experts develop and keep for reuse a library of alternative scheduling segments for each operation. The reuse of a library of scheduling segments is of much importance for the "engineer to order" process where a manufacturer meets the specifications of their customer by engineering and producing the product after an order has been received. Developing a scheduling segment is a complex and time-consuming task, for which scheduling experts can benefit by reusing existing scheduling segments. The objective is to minimize the makespan by combining scheduling segments into a feasible schedule. We propose a new efficient heuristic for addressing this challenge. Previous methods for optimally solving this problem suffered from severe scalability issues, while previous heuristics experienced high rates of infeasibility that hurt both efficiency and performance. The proposed approach integrates a genetic algorithm with a greedy procedure for overcoming these difficulties while enabling, for the first time, the solution of practically sized jobs.

2 - Multi-agent Parallel Machine Scheduling based on Auction

Shudong Sun

A dynamic iterative auction-based approach is developed to solve the multi-agent scheduling problem with parallel machines. In the proposed approach, an auction procedure is established for dynamic jobs participating in a real-time auction. A straightforward and easy-to-implement bidding strategy without price is presented to reduce the complexity of the bid determination. An adaptive Hungarian algorithm is applied to solve the winner determination problem. An analysis is conducted to show that the proposed approach is individual rationality and that the myopic bidding strategy is a weakly dominant strategy for consumer to submit bids. Extensive simulation results show that the developed approach can get high-quality solutions and have considerable stability on large-scale problems.

3 - Scheduling of workers and robots in collaborative assembly lines

Yiting Sun

Industry 5.0 promotes human-centric industries. Human-robot collaboration is a rapidly developing production mode. By combining the strengths of humans and robots, it not only improves production efficiency but also reduces ergonomic risks for workers. We study how to schedule workers and robots in a collaborative assembly line. We formulate a mixed integer programming model and propose an adaptive simulated annealing algorithm. We compare our algorithm with genetic algorithm and artificial bee colony algorithm. The experimental results show that our algorithm outperforms the others. Furthermore, we analyze the impact of the human-machine collaboration on the assembly line balancing plan. We find that the fairness of workload distribution among workers may deteriorate due to human-robot collaboration, which is something to be aware of.

4 - Mixed-model assembly sequencing and operator assignment

Carlos Miguel

Mixed-model assembly lines (MMALs) manufacture several variants of the same product base to meet the varied model-based customer demands. However, this model diversity usually causes fluctuations in the total processing time at some workstations. When these fluctuations exceed the cycle time, work overload is generated. This occurs, for example, when several high processing time models are processed consecutively. Therefore, a careful sequencing of these models is essential to reduce overload. The main objective of the Mixed-Model Sequencing Problem (MMSP-W) is to establish a sequence of the models to be manufactured so that the total overload is minimized.

Manual labor is common in MMALs, where their competence levels determine operator performance. Thus, competence deficiencies may lead to higher processing times and increased work overload. Therefore, competence-driven operator assignment should be considered alongside model sequencing. We achieved this by extending MMSP-W to include operator assignment in its formulation, and performing the assignments to minimize the gap between task competence requirements and the competence levels of operators. Initial findings show that this extension enables appreciation of the influence of operator competency in the overloads generated in a sequence. Furthermore, the extension results in a problem with additional complexity and incremental solving times, which we address by proposing a Benders composition-like heuristic.

■ WC-50

Wednesday, 12:30-14:00 - Room: M2 (building: 101)

E-Commerce

Stream: Retail Operations

Invited session

Chair: Pedro Amorim

1 - Enhancing Retail Strategies through Electronic Uniform Invoice Analysis: A Study on Consumer Behavior and Market Segmentation

Ling-Jing Kao, Pei-qi Chen, Chih-Chou Chiu

As market competition escalates, retailers are compelled to understand consumer preferences more deeply to discern needs accurately. However, limited to internal databases, they lack access to cross-channel consumption data for a comprehensive understanding. This study utilizes electronic invoice records to analyze consumer behavior, predicting product choices in supermarkets. Employing the Self-Organizing Map (SOM) algorithm for consumer segmentation, it groups consumers with similar behavior, enhancing predictive accuracy. Using variables like expenditure and purchase frequency, it constructs Long Short-Term Memory (LSTM) models for channel forecasting. Empirical results show exceptional accuracy in product category prediction. This research aids effective segmentation, providing insights into consumer needs for inventory optimization. Cluster analysis facilitates targeted marketing, benefiting both retailers and consumers. Further validation and updates are vital for practical applications.

2 - From Personalization to Optimization: A Framework for Enhanced Product Recommendations

Atakan Yilmaz, Onur Demiray, Betül Ahat, Ahmet Çınar, Berker Özbek

Pointwise ranking models diverge from conventional recommendation systems by tailoring item rankings directly to individual user preferences, thereby offering nuanced recommendations aligned with user tastes. However, overlooking pairwise, listwise and position based factors in ranking output can diminish the overall user experience. To obtain user-specific rankings while considering the whole ranked list, we propose a framework that synergistically leverages machine learning and optimization techniques. Focused on personalizing product recommendations within the Trendyol app, our approach integrates xG-Boost Classifier and integer programming to derive item scores and optimize rankings while addressing diversity concerns across categories and brands. Our framework starts with using nearly 200 features to learn user action probabilities. Then, an integer programming model determines rankings of products by maximizing expected purchases while ensuring diversification. This process operates in near real-time, updating personalized rankings every 2-3 minutes for 150,000 users. To tackle scalability challenges, we propose an alternative formulation and decomposition algorithm. Lastly, we introduce an ML-based multi-objective optimization framework to extend our focus to other performance metrics such as position-based utilities and clicks, alongside purchases. Rigorously tested via our effective AB testing system, we comprehensively analyze and discuss our results.

3 - Intertemporal Bundling with Patient Customers: A Comparison of Behavioral Response and Normative Equivalence

Burak Gokgur, Ayse Kocabiyikoglu

We consider the problem of a retailer selling products that can be offered individually or in a bundle to a market that comprises heterogeneous customers who differ in terms of their valuations for the products and their patience levels. First, we develop a mathematical model that captures the retailer's expected revenue maximization problem over an infinite horizon in a multi-segment market setting. Then, we present results from numerical experiments that assess the benefits of adopting an intertemporal bundling policy and investigate its behavior with respect to the market structure. Finally, we study, via behavioral experiments, whether human decision-makers are able to fully capture the benefits of offering the bundle at random intervals. Our computational results indicate that intertemporally randomized bundle offer attenuates the negative revenue impact of positively correlated valuations in the presence of patient consumers, thereby elevating the bottom line. Besides, the behavioral experiments show that decision-makers' responses significantly deviate from those of normative counterparts as the heterogeneity in the market structure and the complexity of the pricing mechanism increase.

4 - Channel Switching in Omni-Channel Retailing

Bahriye Cesaret, Armagan Bayram

The evolution of technology has changed the ways customers engage with retailers. Customers now utilize various sales channels in their buying processes. Consequently, retailers are challenged with customers who tend to switch between various sales channels. Omni-channel retailing allows customers to buy products from anywhere and return them anywhere, while allowing retailers to fulfill orders from anywhere. This flexibility enhances the customer experience by integrating all channels, allows retailers to achieve more availability and boosts the sales and traffic of the retailers. However, it also places significant pressure on retailers to streamline their operations efficiently and expedite product delivery to customers. In this study, we explore two omni-channel implementations, namely, ship-from-store and home delivery. Store customers can opt for in-store fulfillment or request home delivery, whereas online orders can be shipped from the fulfillment center or any other store location that maximizes the retailer's overall profit. We further consider that both store and online customers can switch across channels. We construct a dynamic programming framework to examine optimal fulfillment decisions for both online and store orders, accounting for uncertainties in both demand and the cost of shipment to individual customers. We present our results through optimal fulfillment strategies and numerical experiments.

■ WC-51

Wednesday, 12:30-14:00 - Room: M5 (building: 101)

Timetabling 1

Stream: Public Transport Optimization

Invited session

Chair: Sven Jäger

1 - An Integrated Approach to Electric Bus Timetabling and Scheduling for Sustainable Urban Mobility

Gajendra Nagar, Hemant Kumar Suman, Lakshay Lakshay, Nomesh Bolia

Transportation is one of the major contributors to global carbon emissions. This makes it necessary to shift from fossil fuels to renewable energy sources for a sustainable transportation system. Electric buses (EBs) play an important role in this transition because of their lower carbon emissions. But to integrate the EBs into the existing network, two main problems arise: timetabling and scheduling. These problems can be addressed either sequentially or in an integrated way. However, the sequential approach may produce a suboptimal bus schedule due to fixed timetable and operational constraints. Also, due to the fixed departure time, EBs miss their best sequence of trips, which could raise the further requirement for new buses. So, in order to develop an effective bus schedule, both timetabling and scheduling problems should be addressed simultaneously due to their interdependency. In response, this paper proposes an integrated method for solving the timetabling and scheduling problems. Initially, a mathematical model is developed to minimize overall costs, including bus procurement and charging expenses. The developed model uses service frequency as an input to generate a timetable and assign buses. Second, a heuristic algorithm is developed in order to produce the result for large instances. Later, we validated the methodology in Bangalore, India, using a realistic scenario to demonstrate its ability to assign EBs while also generating daily timetables.

2 - Integration of timetable synchronization and vehicle circulation for public transit networks: A novel quadratic semi-assignment problem formulation

Tianqi Li, Lei Nie

In public transit networks, timetable synchronization is crucial for offering passengers attractive transfer services, while vehicle circulation significantly impacts operating costs. These two problems are closely

related and well worth integration since the number of required vehicles is influenced by train timetables, and both focus on service connections. However, there is very limited research on integrating these two problems.

In this paper, we present an integration of these two problems into a novel quadratic semi-assignment problem (QSAP) formulation, based on a simplified time-discretized network. The objective is to simultaneously minimize passenger total transfer time and vehicle operation costs. We include features such as multiple period lengths, flexible transfer connections, and vehicle connections within a pure QSAP formulation. By avoiding the inclusion of additional variables and constraints, this formulation optimally leverages existing algorithms designed specifically for QSAP. Furthermore, we reformulate the problem into a Quadratic Unconstrained Binary Optimization (QUBO) formulation, solved with advanced quantum annealing approaches. Our model is also linearized into an integer linear programming (ILP) format, ensuring compatibility with solvers like Gurobi. To verify the accuracy and computational efficiency of our models, we applied them to numerous virtual case studies and real-world cases from the Beijing Metro Network.

3 - Optimizing Public Transport Timetables: Adaptive Large Neighbourhood Search with Heuristic and Exact Repair Operators

Robin Gaborit, Jiří Spitzer, Yu Jiang, Otto Anker Nielsen

This study introduces an adaptive large neighbourhood search approach for solving path-oriented public transport scheduling with time-dependent travel time and demand data. The decision variables are the departure times of the vehicles from each stop, while the objective function is a weighted sum of passengers' travel time components costs and a penalty cost for violating the desired arrival time window. The mathematical model was developed by Lee et al. (2022). Due to the complexity of this model, solving real-world instances on the fly is challenging for exact solution methods. To address this problem, this study proposes an adaptive large neighbourhood search algorithm featuring five destroy-repair operators. Its main novelty is that two operators employ a heuristic to repair the solution, whereas the remaining three utilize a MIP solver. The operators also differ on which part on the solution they destroy; three of them randomly destroy parts of the incumbent solution, and the other two are more likely to target parts of the solution with a higher contribution to the objective function. The algorithm is implemented and tested on real data from the public transport system of the metropolitan area of Copenhagen, Denmark. Benchmarked against a MIP solver, our solution method outperforms it in all instances. On average, it achieves 7.5% to 17.5% better results in the three largest instances. Our algorithm is also much more stable.

4 - Sustainable Timetabling: Integrating Regenerative Braking into a PESP Model

Sarah Roth, Sven Jäger, Anita Schöbel

While a shift from individual transport to public transport is necessary to reach climate goals, also the public transport system consumes a non-negligible amount of energy. Modern electric motors are able to regenerate energy while braking. In the context of rail traffic, the most efficient way to use the regained energy is to transfer it via the catenary to an accelerating train close by. Therefore, it makes sense to select the timetable so that braking and acceleration processes of trains near each other take place simultaneously. In this talk a new MIP model is introduced that finds a feasible periodic timetable optimizing the usage of energy obtained from regenerative brakes. Assigning arrival and departure times, the model also decides between which pairs of trains a transfer of energy takes place and it maximizes the total brake traction overlap. The new model based on the PESP is compared to previous models that optimize the usage of regenerative energy and computational results are presented. While the usage of regenerative energy profits from synchronized brake and traction phases of two trains, this prevents the transfer of passengers from the braking to the accelerating train. We analyze the tradeoff between energy and travel-time optimization and show first properties of Pareto-optimal timetables for the special case of one transfer station.

Heuristic Algorithms for Combinatorial Optimization Problems I (Contributed)

Stream: Combinatorial Optimization

Invited session

Chair: *Ali Ekici*

1 - Hybrid Genetic Algorithm for Solving The Three-index Assignment Problem

Mohamed Mehbali

The paper introduces the three-index assignment problem (3IAP) consists of assigning n tasks to n machines in n factories provided that a task is exactly allocated to a machine in a factory so that the total cost of allocation is minimal. The 3IAP, extending the classic two-dimensional assignment problem, is established as NP-hard. Due to its computational complexity, innovative heuristics are designed for near-optimal solutions. Applying Genetic Algorithms (GA) to 3IAP evolves a population, seeking optimal or near-optimal solutions over generations. This investigation advocates enhancing their quality by integrating a local search method. The study proposes a hybrid genetic algorithm, integrating GA with a particular local search based on permutations, yielding high-quality solutions in a notably reduced computational timeframe compared to deterministic methods. The efficacy of this hybrid approach is demonstrated through experimental results and comparisons with other optimisation methodologies.

2 - ILSHADE-SPACMA: Improved version of LSHADE-SPACMA

Abdelazim Hussien, Adrian Pop, Fatma Hashim

LSHADE-SPACMA stands out as a highly potent algorithm, amalgamating a refined version of LSHADE with a modified version of CMA-ES. In this study, we endeavor to augment the exploratory capability of LSHADE by incorporating a transfer operator. Additionally, an alternative mutation strategy is introduced to enhance overall diversity. The proposed optimizer, dubbed ILSHADE-SPACMA, undergoes a rigorous comparison with both the original LSHADE-SPACMA algorithm and LSHADE across 12 functions sourced from CEC2022. These experiments are conducted with varying numbers of evaluations—50,000 and 100,1000—while dimensions are set to 10 and 20. The results underscore the robustness of ILSHADE-SPACMA in swiftly converging towards near-optimal solutions within acceptable timeframes.

3 - Bin Packing Problem with Conflicts and Item Fragmentation

Ali Ekici

In this study, we analyze a variant of the well-known Bin Packing Problem where items can be fragmented and some pairs of items cannot be packed into the same bin due to conflicts. The goal is to pack a given set of items into a minimum number of fixed-capacity bins while not packing fragments of conflicting items into the same bin. This problem is called the Bin Packing Problem with Conflicts and Item Fragmentation. We develop a lower bounding scheme based on identifying a maximal clique of the conflict graph for the problem and propose a heuristic algorithm called the Sequential Maximum Degree Packing Heuristic which sequentially packs the items starting from the highest degree item using a mixed-integer model. We test the proposed solution approach on the instances with random conflict graphs and compare its performance against that of the benchmark algorithms in the literature. We observe that our approach outperforms the benchmark algorithms especially when the conflict graph is dense. It provides solutions with up to 13% less optimality gap compared to the algorithms in the literature. Finally, the proposed lower bounding scheme improves the trivial continuous lower bound only if a large maximal clique of the conflict graph can be identified.

1 - Optimizing Earthwork Management for Sustainable Urban Development: A Mixed-Integer Linear Programming Approach

Che-Fu Hsueh, Yunzhu Lin

This study focuses on promoting green, sustainable, and healthy urban development via comprehensive earthwork management, integrating both ready-for-use and over-wet soil. We enhance the latter by blending it with specifically recycled incinerated waste granules and lime, converting unusable wet soil into a valuable resource. This not only saves disposal costs but also notably reduces carbon emissions. Our mixed-integer linear programming model, designed to optimize acquisition, dispatch, and utilization of earthwork from diverse sources, effectively tackles transportation and resource allocation challenges, ensuring efficient earthwork planning aligned with sustainable construction and conservation principles. Applied to an aerotropolis project in Taiwan, our model demonstrated significant cost efficiencies in earthwork acquisition and disposal, achieving considerable savings compared to traditional methods. Sensitivity analyses on different parameters are also provided. This approach exemplifies the integration of innovative waste management and optimization techniques in urban construction, offering a replicable model for future sustainable development projects.

2 - Environmental Models as a Tool for Ecological and Economic Decisions-Making

Marian Reiff, Ivan Brezina, Juraj Pekár

Achieving sustainable development is one of the biggest challenges today. It is also one of the reasons why the green economy has come to the fore in recent years. Therefore, nowadays, it is attractive to formulate new optimization goals based on established economic and ecological priorities, which are incorporated into economic and ecological models, as green initiatives provide an impetus to move away from the traditional understanding of economic processes. This implies the need to modify optimization processes to link economic and ecological approaches to evaluate the economic and ecological efficiency of the decision-making process. The first works since 1960 can be registered in problematics of environmental control via mathematical programming models. For example, individual companies can use management decision-making methods to address previously mentioned issues and formulate ecological-economic structural models, reverse logistics models, more ecologically friendly distribution models, air and water pollution models, eco-efficiency evaluation models (emission regulation), and resource allocation models. This work was supported by the Grant Agency of Slovak Republic - VEGA grant no. 1/0120/23 Environmental models as a tool for ecological and economic decisions making.

3 - Exploring Consumer Preferences for Subscription: Promoting Sustainable Food Alternative for Synergy between Local and Global Communities

Prashant Kumar, Nomesh Bolia

The focus on sustainable health-oriented food choices has become significant on a global scale. The trend towards consuming organic and sustainable products has seen notable growth, particularly catalysed by the impact of the COVID-19 pandemic. Consumers are now willing to pay a premium for organic and sustainable foods. The promotion of these products has the potential to uplift the income of farmers and processors relying on these products, especially in developing nations like India. This work involves a case study in India, with the

motivation of assessing consumers' subscription inclinations to natural sweetener (jaggery). Jaggery prepared from sugarcane juice is an unrefined medicinal sugar with the potential to substitute white sugar across various applications. This survey-based study utilizes structural equation modeling to analyse the impact of utilitarian values, customer attitude, customer awareness, hedonic motives and perceived barriers on subscription intentions. The promotion of jaggery consumption not only aligns with India's commitment to endorse indigenous products with the potential to create rural employment but also contributes to the global efforts towards achieving SDGs, particularly SDG1, SDG8 and SDG13. This research aims to develop a comprehensive subscription model that considers consumer preferences, pricing strategies, economic viability and other adaptive mechanisms to effectively scale this product based on local and global conditions.

4 - Evaluate the Fairness of the Distribution of Health Services for Older People in Italy: A Methodological Approach

Davide Donato Russo

The aim of this methodological proposal is to assess the fairness of healthcare services for various age groups, with particular attention to older individuals and their unique requirements. The significance of pharmacies, hospitals, and para-pharmacies as crucial providers of specialized services underscores the issue of pedestrian access to healthcare services, especially for older adults. Expanding the scope of this methodological approach to incorporate walkability and economic indices is another objective of this study. Fairness and walkability play pivotal roles in establishing an age-friendly environment, particularly for individuals with specific needs such as older pedestrians. This aspect is particularly significant for gaining insights into the accessibility of essential services. In our methodology, we acquired data regarding the distribution of the Italian population across diverse geographical areas and age groups. We then integrated this information with the distribution of health services in Italy. By leveraging the concept of convolution between matrices, we have developed a novel, generalizable methodological approach to analyze the fairness in the distribution of services across various territorial entities, including municipalities, provinces, and regions. We evaluate the concept of fairness, focusing on older people, through the combination of kernel convolution and economic indices for service inequalities (i.e., Gini coefficient).

Demand-responsive public transport 2

Stream: Public Transport Optimization

Invited session

Chair: *Dilay Aktas*

Chair: *Pieter Vansteenwegen*

1 - Designing a hybrid urban mobility system: framework and bi-level model

Seyedehsima Madani, Kris Braekers, Imre Keseru

Although traditional public transportation, known as a fixed-route transit (FRT) system, is a cost-efficient transit mode in areas with high demand, it is often perceived as inconvenient due to the lack of flexibility. On the other hand, demand-responsive transit (DRT) systems, known as a flex-route transit system (e.g. dial-a-ride services), have a high per-capita operating cost due to their personalized nature. To combine the flexibility of DRT with the cost-efficiency of FRT, the development of a hybrid transit system could be considered a solution. This research focuses on such a hybrid systems that integrate FRT and DRT systems, leveraging the advantages of both. In this research, first, a unifying framework that classifies different models of FRT and DRT integration is presented. Second, a bi-level optimization approach is proposed to model the design of a hybrid transit system in which users may travel through a combination of FRT and DRT. At the upper level, decisions are made on the FRT lines to be included in the network and

their frequencies. For a proposed FRT network structure, the possible sequences of travel modes for all users can be identified. At the lower level, for a subset of requests corresponding to users who cannot complete their trips solely by FRT, the routing and scheduling of DRT vehicles and the fleet size are optimized. Preliminary results of a heuristic solution strategy for this model will be presented.

2 - Dynamic capacity planning for demand-responsive multimodal transit

Bernardo Martin-Iradi, Francesco Corman

Demand-responsive multimodal transit offers opportunities to complement existing public transport systems and provide a better service level to passengers while simultaneously making better use of the resources. This study optimizes the capacity of such a system by strategically sizing the required fleet and allocating it to the operating services. We formulate a two-stage stochastic optimization model that plans the transit system and the required fleet in the first stage and optimizes the demand-responsive operations in the second stage. We develop a decomposition-based method that exploits the network-based formulation of the second stage, allowing us to solve practical instances. Results from a case study in Zurich show that jointly designing and operating public transport and on-demand systems can benefit transport operators and passengers. By allocating the system capacity more efficiently, operators reduce operational costs while maintaining or improving the travel experience for passengers.

3 - The Potential of Governmental Regulation on Shared Mobility-on-Demand Systems

Simon Schmidbaur, Fabian Anzenhofer, Robert Klein, Claudius Steinhardt

The growing number of Shared Mobility-On-Demand services has the potential to contribute to a more socially and environmentally sustainable mobility provision. However, this potential may not be fully exploited due to possible conflicts with the objectives of the service providers. Thus, political discourses address regulatory instruments to influence providers' operational planning. This paper analyzes the effects of two currently debated instruments, i.e., the introduction of a minimum pooling rate and a minimum spatial acceptance rate. This analysis is based on mathematical optimization models that we formulate as generalizations of the selective dial-a-ride problem. More precisely, the problem is first captured by a single-period model formulation and then generalized to a multi-period horizon to implement different regulatory strategies. In a comprehensive computational study, we solve the regulated model variants exactly both for artificial and real-world instances provided by our industry partner FLEXIBUS. We evaluate different levels of regulation for both instruments regarding their feasibility and their impact on the Shared Mobility-on-Demand system, and thereby identify their contribution to a conflicting multi-objective environment.

4 - Sustainability-oriented Dynamic Pricing for Shared Mobility-on-Demand Systems

David Fleckenstein, Fabian Anzenhofer, Robert Klein, Claudius Steinhardt

Shared mobility-on-demand (SMOD) systems are expected to make public transport more sustainable, especially in rural areas. From the social perspective, this means that an SMOD system should contribute to providing area-wide, reliable, and non-discriminatory access to mobility. In ecological terms, the main aim is to decrease emissions per passenger kilometer. Finally, economic efficiency must also be considered to limit the subsidy requirements. Since providers typically offer customers multiple fulfillment options, i.e., rides with alternative pick-up times, dynamic pricing can be applied to actively steer demand, and thereby, improve the system performance. Operationally, an integrated demand management and vehicle routing problem arises, which features sustainability-based objectives in addition to the usual profit maximization. In this talk, we discuss the challenges associated with dynamic pricing in this multi-objective setting and present algorithmic strategies to tackle them. We evaluate our approaches based on real-world data from a rural SMOD provider.

1 - Pricing, Admission and Repositioning in Ride-Hailing Networks: A Deep Reinforcement Learning Approach

Thomas De Munck, Jean-Sébastien Tancrez, Philippe Chevalier

We consider the problem of a ride-hailing platform (e.g., Uber, Lyft) that connects supply with demand over a network of locations. To this aim, the platform makes pricing, customer admission, and driver repositioning decisions. The customers are impatient and have distinct willingness to pay. The drivers can be repositioned by the platform, or can choose to relocate to other locations according to their own choice. We formulate this problem as a discrete-time Markov decision process, and find a near-optimal policy by combining mathematical optimization with deep reinforcement learning. Following our approach, we first find a heuristic policy by solving repeatedly an optimization problem based on the expected values. Then, we train two neural networks to replicate the heuristic policy, and learn the associated value function. We finally improve the policy further through the Proximal Policy Optimization algorithm. By applying our model to real data from New York City, we demonstrate the effectiveness of our approach in comparison with alternative methods. In addition, we explore the interplay between pricing, customer admission, and driver repositioning, and evaluate the effectiveness of these decisions in balancing supply and demand.

2 - A Simulation based Decision Support System for Logistics

Emre Çimen, Gurkan Ozturk, Onur Kaya

The study is related to raw material procurement and product shipments of a steel mill. These materials arrive at the factory's port and are transported from the port to the factory by trucks. The aim is to utilize cranes efficiently, reduce costs, and minimize queues. The system reads parameters related to ports, logistics, and factories from Excel and uses them for the simulation model for different scenarios. This includes ship details such as arrival dates, loading/unloading information, coil/sheet numbers and weights, and assigned port numbers. For facilities, it involves crane-ship assignments, operational details for various processes, and compatibility between coils and trucks. The system allows users to input data for different scenarios. The model is transformed into a functional system using Python with the SimPy library. Key performance indicators are analyzed through graphs and tables by comparing various parameters. This includes calculating queue lengths, waiting times, ship completion durations, demurrage rates, and costs, and exporting results to Excel. Additionally, some artificial intelligence methods such as SVM, Random Forest, Artificial Neural Networks, or PCFs will be added to the system to make predictions related to these key indicators.

3 - Prioritization of traffic crash hotspots for intervention

Yehezkel Resheff, Mali Sher, Nicole Adler

Traffic crashes remain a major cause of preventable loss of life and injury. Many policy and intervention efforts aim to reduce the number and severity of collisions. Of these, the most direct is the identification and correction of hotspots of severe crashes. We present data from the 20 largest cities in Israel, spanning over a decade, showing that locations of clusters of light and property damage crashes have a risk of a severe crash in the following year that is comparable to that of clusters of severe crashes. This has immediate policy implications, as we should rethink the intervention strategy that currently predominantly considers severe hotspots. Next, we apply machine learning to model the probability of having a future severe event at a cluster, given the known characteristics of the location and the previous accidents that

occurred. The quality of the model is shown to differ between types of clusters, such as severe vs. minor, intersection vs. non-intersection, etc. Finally, the problem facing a decision maker is how to use a given budget and prioritize clusters for intervention, based on the risk scores provided by the model and their type-dependant uncertainties, as well as the type-dependant cost of intervention. The overall aim of the policy is assumed to be maximization of the total reduction of expected future severe crashes, but extensions that consider fair spread of resources are also considered.

4 - Deep Learning Based Hybrid Genetic Algorithm for the CVRP

Adrien Pichon, Alexandru Olteanu, Marc Sevaux

Over the last years, hybrid genetic search (HGS) algorithms for the vehicle routing problem (VRP) and its variants have demonstrated encouraging results in particular with the use of a route-first-cluster-second heuristic. As an individual is represented by a "grand tour" (TSP Solution), the advantages of this method are an easiness regarding the population management and crossover operators combined with an optimal split method for the transition from an individual to a full solution. The goal is to improve the efficiency of this method using a trained deep learning model to identify good individuals in the population, thus avoiding the need to switch search space and saving computational time. To this end, a reverse split method is used to switch freely between population and solution space to train the deep learning model using cost evaluation and feature extraction.

1 - Last-Minute Crew Rescheduling: Model and Heuristic Approach

Liyun Yu, Carl Henrik Häll, Anders Peterson, Christiane Schmidt

We consider crew scheduling on the day before operation: because of a lack of train drivers (e.g., due to sick leave) crew members need to be rescheduled. We are given a feasible crew schedule for a subset of the drivers, a set of unassigned tasks, and a set of standby drivers with fixed start and end time of their working hours. We aim to generate a new crew schedule with as few unassigned tasks as possible — which will in turn decrease the number of trains to be cancelled. We build a Mixed Integer Linear Programming (MILP), which we solve using the commercial solver Gurobi 11.0, and we develop a heuristic approach based on Tabu Search. We consider the same restrictions for the MILP model and our heuristic, this includes constraints on the total working hours, on break duration, maximum working time without a break etc. The data of a one-day schedule is provided by Mälartåg with 153 drivers in total, in which there are 16 standby drivers with fixed depot, start and end working time. For an instance with 11 drivers being on leave, we can assign all but 5 tasks (from a total of 37, which were unassigned after the leave), and we obtain a result in 23 seconds. We compare the results, computational time and space between our model and approach to show that our Tabu-Search-based approach can achieve a 'good-enough' result with less time and space needed.

2 - Optimal use of in-house and outsourced vehicles

Kritika Karwasra, Narayan Rangaraj

Rail is a good mode of transport especially for bulk commodities like cement and steel, over medium and long distances. However rail services are subject to delayed deliveries, especially due to unavailability

of wagons (set of wagons, also known as rakes). To address these issues, companies invest in railway wagons. This fleet is maintained by the shipper, but the movement is by the railway company with a rebate on transportation cost. Procuring such a fleet requires a significant financial investment. We consider the case where some in-house rakes are procured that are used along with outsourced resources. With this mixed fleet composition and considering the benefits offered by in-house rakes over outsourced rakes, an operational question is: how should we allocate in-house and outsource rakes to various demands? We examine several allocation policies considering 1) distance 2) cost rebate through use in-house fleet and 3) overall transportation cost. A simulation modeling tool is used to assess different policies under various scenarios considering demand patterns, turnaround time, waiting time of locomotives and availability of outsourced rakes. The study also explores how the randomness associated with these parameters affects these policies. The general question is that of optimal use of limited internal capacity along with outsourced resources in a cost effective way.

3 - The Green Locomotive Assignment Problem with Deadheading on Trains

Gisling Stefan, Fatih Kocaturk, Ninja Soeffker, Jan Fabian Ehmke

Reducing energy consumption has become an important goal in all sectors of the economy and especially in transportation. Our goal is to examine potentials for energy reduction in railway operations. We propose the Green Locomotive Assignment Problem (GLAP) which aims at minimizing overall energy consumption through efficiently allocating locomotives to scheduled trains. The objective covers all key aspects of locomotive scheduling, with energy consumption during light-traveling trips standing out as the primary cost driver. Light-traveling occurs when a locomotive needs to relocate to a different station and therefore moves without any train attached. The Davis equation, a physical model that factors in the resistance encountered by a moving train, is augmented with track gradients to accurately compute energy consumption during light-traveling trips. We directly minimize energy consumption and compare this to the conventional approach of minimizing light-traveling distance. Additionally, we propose a model variation of the GLAP, which incorporates the practice of deadheading on trains. Deadheading on trains refers to the attachment of locomotives to trains for repositioning purposes without utilizing their engines and has the potential to reduce energy consumption. We propose mixed integer programs and test them on small and medium sized real-world instances using historical planning data and detailed gradient information from the Austrian Railway network.

Forecasting for the middle mile

Stream: Optimization at Amazon

Invited session

Chair: Inaki Estella Aguerri

Chair: Daniel Guimarans

1 - Coherent forecasting for Supply Chain Optimisation

Hermína Petric Maretic, Sidharth Gupta, Juba Nait Saada, Chris George

The precision of planning and decision making in Amazon is heavily reliant on sophisticated forecasting methods. These forecasts, often made independently, enable different aspects of logistic chain, such as truck scheduling or labor planning. However, in reality, they forecast values that often interact or depend on each other, or in the least contain strong correlations. We explore various methods to take these relationships into account, such as hierarchical reconciliation, combinations of forecasting and simulation, modelling input-output system constraints, as well as joint time series forecasting approaches based on diffusion models.

2 - Demand forecasting for Resource Planning and Dynamic Decision Making

Inaki Estella Aguerri, Filippo Fedeli, Timoté Vaucher, Giorgio Polla, Thomas Ovestad

Every week, planning teams in Amazon need to allocate the resources (e.g., schedule trucks, plan for labor) required to deliver customer orders in a timely and cost effective manner. This planning process is based on demand forecasts, that estimate the packages to be shipped across the network. As one gets closer to the delivery date, real-time signals on the progress of the plan execution become available. This opens the door to update the forecast and refine the resource planning continuously to improve cost and increase effectiveness. However, regular plan changes need to account for uncertainty and end-to-end impact across the network to avoid plan fluctuations and local decision making. In this talk, we explore different methodologies to generate the demand forecast and its refreshes with focus on accuracy, coherence, uncertainty quantification and reduced variability, as well as its combination with different resource planning strategies for regular updating.

3 - Transit Estimation Models for Transportation Planning

Carlos Sanchez Sanchez, Mounir Boujrad, Tim Forbes, Olle Green, Madhavan Sriram, Chris George

Decision making in Transportation, including network design, reactive adjustments during execution, or post-run analysis, requires an understanding of the vehicle transit time, carbon impact, and risks. In this talk, we explore a unified approach for the estimation of such factors that leverages the information available from vehicle sensors and other geospatial data at each time horizon. We propose a model that combines routing and predictive algorithms to provide transit estimates for both connections between Amazon locations as well as unseen routes between third-party vendor connections. We describe how we deal with noisy telematic signals and sparse ground truth, the machine learning approaches to work with road-level data, and the mechanisms to represent the variability inherent to a prediction that depends on the road conditions and driver behaviour.

4 - Foundation Models for Time Series Forecasting

Chris George, Claudio Coppola, Jason Omedes, Juba Nait Saada, Sergio Alvarez Balanya

Maintaining a complex transportation network at global scale involves a large number of planning processes, each requiring visibility on how expected demand from customer orders will flow through local regions in the transportation network. For example, planning labour to process warehouses requires visibility on packages arriving at each warehouse. While traditional forecasting approaches rely on statistical or machine learning models independently optimised to forecast for a single granularity and horizon, they can require significant historical data for the granularity in question and cannot adapt well to new time series, inhibiting the expansion of the network to new countries or demand streams. In this work we explore a new approach to time series forecasting, where a single deep neural network trained on large collections of time series datasets is used to provide robust forecasts across many granularities and horizons. Inspired by Large Language Models and the ability of Transformer architectures to model long range dependencies in textual data; we hypothesise that adapting the Transformer architecture to numerical data and training them on large time series datasets can allow a single model to reliably forecast across multiple granularities and horizons and even outperform the traditional multiple-model approach, particularly in cases where little historical data is available.

1 - Rethinking Cyclic Structures in Liner Shipping Networks

Daniel Wetzel, Kevin Tierney

Liner shipping networks are a central feature of modern supply chains that consist of cyclical, periodic services operated by container vessels. This specialized, cyclical structure eases planning for both shipper and carrier, but the combination of cyclical planning with the available time windows at ports can lead to inefficient operations. We propose to relax the cyclical assumption and allow vessels to move between services to avoid inefficient connections without interruption to container flows. From the view of a shipper, the cyclical and periodic properties of the services still hold, and the liner carrier can offer a more efficient overall network. The ensuing optimization problem consists of a combined vessel routing problem and cargo allocation problem, resulting in large and challenging instances. We model the problem using mixed-integer linear programming and use an expanding horizon heuristic to find starting solutions for our model. We use real-world data to show that giving flexibility to a liner network can result in a significant cost reduction over standard cyclical schedules.

2 - A Novel Clustering Approach for VRPs Considering CO2 Emissions

Sara Joosten, Alexander Hübner, Fabian Schäfer, Clemens Thielen

The transportation sector is a major contributor to CO2 emissions. We consider a pollution routing problem within the scope of the capacitated vehicle routing problem by explicitly considering CO2 emissions. We propose a novel MIP-based clustering approach that assigns customers to tours minimizing the estimated resulting CO2 emissions. Our approach extends the method of Fisher and Jaikumar by approximating the weight of the truck (including curb and payload weight) at each detour. That way it can be incorporated into any MIP-formulated routing problem (e.g., location routing problems, delivery and pickup problems or inventory routing problems) making it essentially different from other heuristics. After evaluating different seeding strategies, we perform tests on the Solomon benchmark and the XML dataset. Comparisons with known optimal solutions as well as a continuous approximation method are also drawn.

3 - Shortfall Allocation and Safety Stock Optimization for Capacitated Joint Replenishment

Birger Raa, Tarik Aouam

We consider a periodic review inventory system in which multiple customers are jointly and periodically replenished from a single supplier by a vehicle with limited capacity. The customers have stochastic demand, and at every replenishment, their inventory is supposed to be filled up to a so-called 'base-stock' level. However, when their cumulative demand between replenishments exceeds the vehicle capacity, it is impossible to replenish all the customers up to their base-stock and shortfall occurs. When the distribution of this shortfall is approximated with a mass exponential function, closed expressions for the expected inventory holding costs and stockout costs at the customers can be derived. This allows us to optimize the base-stock levels of the customers, minimizing the total holding and stockout costs. As a result, we can evaluate several rules-of-thumb for allocation of the shortfall across the customers. Moreover, we can optimize the shortfall allocation in an iterative procedure. In an extensive computational study, we compare the cost effectiveness of various shortfall allocation rules across a wide range of scenarios where the customers have varying cost parameters and storage capacity limitations. Furthermore, the convergence of the iterative shortfall allocation optimization procedure is inspected, and the accuracy of the approximation is evaluated using simulation experiments.

4 - Dynamic Order Allocation to Locker Boxes Under Uncertain Pick-Up Times

Simona Mancini, Margaretha Gansterer

Delivery to locker boxes has become very popular in e-commerce as it is beneficial for companies and also convenient for customers who can flexibly pick-up their parcels. In our study we assume that parcels can be picked-up within three days after delivery. Afterwards, the parcel is removed by the company. However, the uncertainty on the pick-up time negatively affects order acceptance and allocation strategies of the company, yielding to potential inefficiencies of the overall system. To deal with this issue, we study the dynamic order allocation to locker boxes under uncertainty on parcel pick-up times, formulated as a multi-stage stochastic optimization problem, dealing with three types of decisions: (1) whether to accept or not an order, (2) when to deliver it, and (3) to which locker to assign it. To solve this problem, we provide an integer programming classification algorithm which, tuned on simulated optimal decisions made by an oracle model, derives decision rules to be dynamically applied. Results are compared against standard classification algorithms and parametric functions. Furthermore, valuable managerial insights regarding assignment decisions of logistics providers are presented.

1 - Analysing the optimal time of purchase in case of increasing carbon dioxide prices

Anna Uhrmeister

The awareness of climate change and the corresponding need for climate protection have become omnipresent for companies nowadays. In 2005, the European Commission established the European Union Emissions Trading Scheme (EU ETS), in order to mitigate the effects of anthropogenic climate change and render them more predictable. From 2027, as a result of the so-called Green Deal, companies will no longer receive subsidies and will be responsible for paying the full costs of greenhouse gas emissions. The ramifications for companies are still uncertain. Starting from this, the aim of the research endeavors to delve deeper into the examination of the impact of greenhouse gas emission costs on German companies. It is assumed that the effects will be most significant in carbon intensive productions. Taking this into consideration, this research will model and analyse an average company in the steel industry. Along with the implementation of the EU ETS, companies are faced with the challenge of making decisions on the purchase of European Emission Allowances (EUA's) or the investment in lower-emission technology. The study aims to provide an overview of the range of strategies a company is faced with. Subsequently, a selection of possible scenarios are analysed e.g. the optimum time of purchase, considering capital commitment costs. Furthermore, the uncertainty caused by fluctuations in EUA's and fluctuating raw material prices are considered.

2 - The Impact of Companies' Performance on the Implementation of the Green Deal in the regions of Europe, North America and Asia-Oceania

Raminta Vaitiekuniene, Kristina Sutiene

The European Green Deal envisages ensuring climate neutrality by 2050. This includes a modern and competitive economy based on a clean environment and neutralized climate. Companies are playing a significant role in this process. The Green Deal initiative encourages other countries to move towards a green economy, so all countries can

use the concept of the Green Deal as a symbol of sustainability. The purpose is to evaluate the financial and innovation performance of the largest European, North American and Asian-Oceanian companies, revealing how companies contribute to the implementation of the Green Deal. Systematization of scientific literature, selection of input and output variables based on the results of scientific literature, analysis of statistical relationships, and panel regression models as the main research methods are applied to achieve this purpose. The results show that companies from all three regions (European, North American and Asian-Oceanian) significantly concur with the implementation of the Green Deal. Return on assets and leverage as financial performance indicators significantly influence the results of environmental performance. Research and experimental development expenditure as an indicator of innovation performance has a significant impact on environmental performance as well. Companies should find more opportunities to pursue financial, innovation and environmental goals together to achieve long-term climate goals.

3 - Data Envelopment Analysis in Management Accounting: New Frontiers Exploring Industry Characteristics

Claire Cui

Since the 1980s, Data Envelopment Analysis (DEA) has been a staple in management accounting for performance efficiency by converting inputs into outputs, typically within production processes. However, recent access to extensive accounting databases has shifted DEA applications to financial data (FinDEA), contrasting firms across industries. This evolution prompts two inquiries: the influence of chosen performance metrics on FinDEA's business assessment and the impact of industry traits on these evaluations. Our study assesses the coherence of ten FinDEA models across six sectors, revealing that FinDEA scores are consistent within specific performance metrics. Additionally, industry nuances distinctly influence FinDEA outcomes. These insights inform the application of FinDEA in future management accounting research using large-scale financial data.

4 - Developing knowledge-driven hybrid models for corporate towards ESG

Lai Li wen, Huang Sun-weng., Ho Hsiao Hua

Nowadays, whether corporate can effectively implement and develop ESG has become a basic public evaluation indicator. However, the implementation and development of ESG has a significant impact on business performance. How to develop ESG to enhance corporate performance has become a focal point global companies stress. Therefore, this study develops a knowledge-driven hybrid model to explore the key path to the development of ESG in improving corporate operating performance. First, we define the target company and use m-VIKOR technology to conduct a comprehensive assessment of the company's ESG and operating performance. Second, we use ESG and business performance analysis to differentiate target companies. Third, a study is conducted based on the core and rules of data mining exploration influence. Finally, we develop an effective development path based on the rules. This research will help companies implement ESG development and help with climate change.

Machine Learning in Machine Scheduling

Stream: Project Management and Scheduling
Invited session

Chair: *Aykut Uzunoglu*

1 - Integrating Simulation, Optimization and Reinforcement Learning for a General Class of Scheduling Problems

Haitao Li

We study a general class of stochastic scheduling problems that include various machine scheduling and resource-constrained project scheduling problems under uncertainty as special cases. There are two general strategies to solve the addressed class of scheduling problems with stochastic activity durations: open-loop and closed-loop. Although closed-loop policy is theoretically advantageous over open-loop policy, as computing an optimal closed-loop policy requires solving the Bellman equation, which suffers the well-known "curse-of-dimensionality" for large instances. In this paper, a Markov decision process (MDP) model built upon discrete-time Markov chain (DTMC) is developed for the addressed class of problems. To tackle the curse-of-dimensionality of obtaining the exact closed-loop policy to the MDP model, we present a general approximate dynamic programming (ADP) framework that integrates simulation, optimization, and reinforcement learning, called Sim-Opt-RL, to provide quality and computationally tractable closed-loop policy. We implement the Sim-Opt-RL framework for a well-known and well-studied stochastic resource-constrained project scheduling (SRCPSP), with a custom designed genetic algorithm (GA), which outperforms the existing closed-loop algorithm, and is competitive with the state-of-the-art open-loop algorithms for the SRCPSP.

2 - Cooperation and competition in two-agent scheduling with parallel batching

Renjie Yu, Daniel Oron

We study single-machine scheduling problems involving two competing agents sharing a batching machine. This machine can handle at most one job from each agent simultaneously. Our focus is on two due date-related scheduling criteria: the number of late jobs and the total late work. We investigate two variations for each problem: minimizing the combined objectives of both agents, and minimizing the objective of one agent while imposing an upper bound on the other agent's objective. All four versions of the problem are demonstrated to be strongly NP-hard. To address this complexity, we devise efficient Mixed-Integer Linear Programming (MILP) formulations, and employ constructive algorithms and Tabu Search for approximate solutions. A comprehensive numerical analysis validates the effectiveness of the approximation algorithms.

3 - Minimizing the number of late jobs and total late work with step-learning

Johnson Phosavanh, Daniel Oron

We study single-machine scheduling problems with step-learning, where an improvement in processing time is experienced if a job is started after a job-dependent learning-date. We consider minimizing two functions: the number of late jobs and the total late work, and we show that when at least a common due-date or common learning-date is assumed, the problem is NP-hard in the ordinary sense; however, when both are arbitrary, the problem becomes strongly NP-hard. For each of the problems where at least one of the dates is assumed to be common, we analyze the structure of an optimal job schedule with and without idle time and propose pseudo-polynomial time dynamic programming algorithms. We also show that the problem of minimizing the weighted number of late jobs with step-learning can be solved with a minor change to the algorithms for the unweighted case. In addition to this, we show that when a common due-date is assumed and no idle time is allowed, the problem of minimizing the total late work is equivalent to that of minimizing the makespan. Furthermore, we provide a more efficient algorithm to solve the problem of minimizing makespan under the assumption of a common learning-date than the one in the existing literature.

4 - Applying Machine Learning in Machine Scheduling - Improving the Decision-Making of a Serial-Batch Scheduling Problem

Aykut Uzunoglu, Christian Gahm, Axel Tuma

Heuristic algorithms are commonly used in practical applications of combinatorial optimization to achieve efficient problem-solving. However, these heuristics have limitations when applied to interleaved and computationally hard problems. To address these shortcomings, we propose enhancing decision-making by using Machine Learning (ML)

models. We demonstrate the effectiveness of this approach on a complex example of a serial-batch scheduling problem, which involves deciding the grouping of jobs (i.e. batching) and sequencing of batches (i.e. scheduling). The maximum potential of ML models can be exploited by strategically applying them at various junctures within the problem-solving process. We analyze three stages to integrate ML models to improve decision-making. Firstly, ML models are used to anticipate solutions for base-level nesting problems posed by the batching decisions. Secondly, the models are used to tune the parameters of the top-level problem's solution method circumventing time-intensive search approaches. Finally, the most suitable solution method is selected for a problem instance by creating ordinal preferences between solution methods based on model predictions. The effectiveness of using ML models to improve decision-making at different stages of the scheduling problem is highlighted by our empirical evaluations.

Retail Inventory Management III

Stream: Retail Operations

Invited session

Chair: *Sila Cetinkaya*

1 - The Scheduled Joint Replenishment Problem

Miguel Chastre, Albert Schrottenboer, Christina Imdahl, Tom van Woensel

We focus on a stochastic Joint Replenishment Problem setting with a single item, one warehouse and multiple retailers facing compound Poisson demand. The novel aspect of this setting is that the retailers' opportunities for replenishment are constrained by cyclical schedules. We model the underlying Markov Decision Process and determine the optimal joint replenishment policy for small instances via a value iteration approach. Our numerical analysis investigates the influence of schedule attributes on the structure of the final solution. To address larger instances, we propose an iterative solution method that makes use of a reduced state space.

2 - Optimizing Inventory Strategies for Perishable Products: A Comprehensive Model Integrating Freshness Dynamics and Economic Value

Matan Shnaiderman, Yael Lahav, Elad Harison, Jacob kobe Harush

Perishable products are characterized by a predetermined expiration date, beyond which their economic value declines, rendering them unusable. This paper identifies two categories of perishable products: those consumable before expiration but hazardous post-expiry (e.g., medical products), and those with freshness degradation over time, becoming unusable after their shelf life (e.g., agricultural products). Despite these distinctions, both types may be treated collectively due to their shared limited shelf life, impacting their marketability. The study introduces a model where a retailer manages the demand for a perishable product, considering its freshness level and selling price as multiplicative components. Further, the paper explores how decisions related to quantity optimization and profit maximization influence the order quantity. The model facilitates retailers in determining the optimal inventory level to maximize their profits.

3 - On the Impact of Risk-Attitude when Dealing with Stockouts

Sila Cetinkaya

We examine alternative approaches for dealing with excess demand through the lens of a retailer whose risk-attitude is modeled explicitly. With representative risk-neutral and risk-averse newsvendor models, we pursue a comparison between two basic stockout policies (lost-sales versus backorders) in terms of financial metrics as well as metrics

that relate to inventory availability. Depending on the risk attitude and particular cost parameter relationships, we explore settings that reveal the superior way for handling stockout scenarios. We discover analytical takeaways that hold in general and report numerical findings that reveal resiliency of the superior stockout policy.

Container Stacking and Yard Planning III

Stream: OR in Port Operations

Invited session

Chair: *Christopher Expósito Izquierdo*

1 - Decision support system for managing integrated yard problems

Christopher Expósito Izquierdo, Israel López-Plata, Airam Expósito Márquez

The optimization of storage spaces in a terminal is a crucial factor for achieving high performance in its logistical operations. Temporary storage at a terminal is facilitated through a logistical structure known as a yard, where containers are stacked in blocks. The significance of this logistical infrastructure is underscored by the substantial volume of containers managed; for instance, nearly 2000 million tons of containers were stored in ports in 2022. The operations involving container movement and storage entail the coordination of various entities, including vehicles, yard cranes, and others. This complexity gives rise to a range of intricate logistical challenges that warrant attention. This work presents a decision-support system aimed at managing, analyzing, and optimizing container storage and movement in the yard of a maritime container terminal. The system provides a detailed overview of the yard status and enables planning for future operations based on expected arrivals and departures of containers, thereby optimizing available space and reducing vehicle movement and associated emissions. The proposed system integrates a set of optimization techniques such as optimization models, heuristics, or metaheuristics, with the primary goal of addressing various yard problems such as block relocations or vehicle movement. Lastly, this decision-support system is integrated as a subsystem within a digital twin designed to manage all logistic operations within a port.

2 - Stochastic Modeling and Analysis of Two-phase Operations in Container Terminal with Automated Lifting Vehicles

Vishal Bansal, Govind Kumawat, Divyansh Tripathi

Container terminals around the world are embracing automation to improve their efficiency and throughput performance for dynamic business requirements. However, to achieve the desired cost and operational efficiency of an automated container terminal, a thorough analysis of its performance under various design parameters is necessary at the design stage. In this paper, we propose a novel queuing model for the performance analysis of a container terminal that uses automated lifting vehicles for container transportation. A special type of two-phase server is used to capture complex two-phase operations of quay cranes, automated lifting vehicles, and stack cranes, which were ignored in previous studies. Since existing methods cannot solve our resulting queuing model, we develop a new network decomposition-based approach to solve it. First, we validate the proposed analytical framework by developing a simulation model and find that it is quite accurate with a less than 5% average absolute percentage error in the average throughput time. Next, we quantify the value of accurately modeling the two-phase operations of resources in a container terminal. In our numerical analysis, we find that ignoring two-phase operations can lead to an overestimation of the average throughput time from 25% to 65%. Thus, our new modeling approach assists terminal designers in accurately estimating the performance measures.

Applications to Economics and Finance

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: *Stavros A. Zenios*

1 - A Market-based Calibration of Capital Requirements

Andrea Consiglio, Mahmoud Fatouh, Simone Giansante

This study introduces a market-based calibration approach for risk-based capital requirements under Basel III reforms. An advanced Merton Distance-to-Default model, modified for non-normal asset distributions, estimates the minimum leverage and risk-weighted capital ratios to maintain a default risk tolerance of 0.1%. This market-oriented method externally evaluates asset uncertainty and default risk, overcoming the limitations of internal models, which often underrate systemic risk in banking. The paper also integrates a novel optimization model to align capital requirements with actual equity levels, ensuring global solution convergence by transforming the initial discontinuous, non-linear model into a smooth convex programming framework. This approach enhances the robustness and reliability of determining capital requirements in the banking sector.

2 - Does Sovereign Debt Consolidation Shape Firms' Credit Cost?

Claire Economidou

This paper studies the effect of sovereign debt on corporate borrowing cost. We develop a theoretical model of a global financial intermediary sector which is tested using data on global syndicated loans for a large panel of firms, banks and countries. Our evidence shows that for government debt around 75 per cent of GDP, any additional percentage increase burdens firms borrowing cost by 11.73 basis points. The effect becomes more pronounced for firms and banks located in the same country, while the degree varies depending on the firm's size and profitability. Overall, results underline that the cost of loans is a relevant mechanism through which government debt affects real economic activity.

3 - Achieving robustness by searching for the right amount of shrinkage in minimum variance portfolios

Xiang Zhao, Selin Ahipasaoglu

We study the minimum variance portfolio optimisation problem, wherein the covariance matrix is subject to a degree of uncertainty, possibly due to estimation errors and the presence of outliers. Classic solutions mitigate such errors through a rank-one shrinkage matrix, constructed using dual variables from a related constrained optimisation problem. Inspired by this, we propose a model that permits varying degrees of matrix shrinkage and identifies the most effective shrinkage scale based on the in-sample performance. Moreover, we identify sufficient conditions that guarantee that the updated (shrunk) covariance matrix remains positive semi-definite, and obtain a practical range for the scale of the shrinkage. Our numerical experiments on out-of-sample data demonstrate that portfolios generated by our model typically exhibit lower levels of short selling and higher Sharpe ratios compared to existing methods. Additionally, they outperform in key risk metrics, such as Value-at-Risk (VaR) and Conditional Value-at-Risk (CVaR). This highlights our approach's effectiveness in addressing estimation uncertainties and its potential to redefine investment strategies in volatile markets.

4 - Gender as a tool for diversification*Ana Escribano, Antonio Díaz, Rocio Hidalgo*

This study investigates the impact of managerial gender on portfolio risk, based on the assumption that women are more risk averse than their male counterparts. The research focuses on a key question: Does this risk aversion manifest itself in the stock market performance of firms that are majority-led by women? To answer this question, we constructed two distinct portfolios based on the gender of top managers: one composed of predominantly female-led companies and one composed of exclusively male-led companies. The selection of companies was based on MSCI's annual global gender diversity reports, and the analysis was conducted over a sample period from 2018 to 2022. Portfolio risk was assessed using the value-at-risk (VaR) metric, with dynamic optimisation procedures applied through an AR(1)-EGARCH(1,1) model to minimise variance. Our results reveal that portfolios composed of predominantly female-managed companies exhibit lower risk, as measured by VaR, compared to portfolios of male-managed companies.

■ WC-64*Wednesday, 12:30-14:00 - Room: S16 (building: 101)***Heuristics for Vehicle Routing 1**

Stream: VeRoLog - Vehicle Routing and Logistics

*Invited session*Chair: Rossana Cavagnini**1 - Exact and Heuristic Methods for the Hierarchical Multi-Switch Multi-Echelon Vehicle Routing Problem***Marduch Tadaros*

This presentation covers a newly introduced variant of the Vehicle Routing Problem - the Hierarchical Multi-Switch Multi-Echelon Vehicle Routing Problem. It is a real-world problem originating from the policies of a Nordic distribution company and includes; a single depot, a non-predetermined hierarchy of intermediate facilities, and two different fleets consisting of homogeneous depot and homogeneous local vehicles pulling swap-bodies. The central depot dispatches vehicles with attached swap bodies, which can either directly serve customers (if only one swap body is attached) or visit switch points to transfer loaded swap bodies to local vehicles. The local vehicles then serve customers with the transferred swap bodies, while the original vehicle continues serving customers with the remaining loaded swap body. The presentation will cover the problem and model formulations, properties and difficulties in solving it using a commercial solver, solution approaches for realistic-sized instances, and decomposition-based methods to generate lower bounds and evaluate the performance of heuristic algorithms.

2 - Improving a Hybrid Genetic Search for the Capacitated Vehicle Routing Problem*Lars Magnus Hvattum*

An open-source implementation of a hybrid genetic search is currently among the very best heuristics for the capacitated vehicle routing problem. While being highly efficient and effective, the code is also relatively simple. It is therefore an interesting challenge to improve the performance of the heuristic while making as small changes to the code as possible. Two such improvements can be found by analyzing, respectively, a cross-over operator and a splitting procedure. An improved cross-over operator is shown to reduce gaps to best-known solutions by 4.2%, and an improved splitting procedure is shown to reduce gaps by an additional 3.9%. In both cases, changes to the implementation is in the order of tens of lines of code.

3 - A Matheuristic for the Edge Set Vehicle Routing Problem With Time Windows and Variants*Rossana Cavagnini*

To reduce emissions, traffic, and noise, municipalities and governments are imposing fees and toll schemes to logistic companies for accessing particular roads. Because such measures increase delivery costs, transportation companies have to consider them when planning routes. In this talk, we address the edge set vehicle routing problem with time windows (ESVRPTW) initially introduced by Reinhardt et al. (2016). The ESVRPTW is a generalization of the vehicle routing problem with time windows in which a fixed cost must be paid for accessing a set of edges.

We propose an improved formulation for the ESVRPTW, new variable fixing techniques, and new valid inequalities. We introduce a new variant of the ESVRPTW to represent urban contexts in which waiting at customers for the opening of their time windows is not allowed. To solve these problems, we present a matheuristic, called MS-LBM, that consists of a multi-start local descent framework that uses a local branching scheme.

In addition to its flexibility in solving all ESVRPTW variants addressed in this talk, MS-LBM provides high-quality solutions faster than a commercial optimization solver and finds new best-known solutions. With an extensive computational study, we derive insights into how allowing waiting at customers affects the edge-set activation and routing decisions depending on the type of infrastructure for which fixed costs must be paid.

1 - Humanitarian operations: How can research help them become more efficient, effective and sustainable?

Maria Besiou

In the last decades, the impact of natural and manmade disasters has been increasing and so does the research in the field of humanitarian logistics. But what are the challenges that humanitarian logistics face in practice and where is the research going? Is there an alignment between research and practice or a gap?

By reviewing papers on humanitarian operations, problems raised by practitioner conferences and webinars, and conducting a survey of the author community on the topic, we link these problems with the literature developed in our field. We also identify characteristics of papers that close the gap between practice and research. We then go deeper into some research projects that have affected practice helping it to become efficient, effective, and sustainable.

Chair: [Jinal Parikh](#)

1 - How to compute confidence intervals for quasi-Monte Carlo estimators

Pierre L'Ecuyer, Marvin K. Nakayama, Art B. Owen, Bruno Tuffin

Randomized Quasi-Monte Carlo (RQMC) sampling provides unbiased estimators whose variance often converges at a faster rate than the standard Monte Carlo estimators as a function of the sample size n . But computing valid confidence intervals is not obvious because the n observations are dependent and the central limit theorem does not apply in general as n increases. A popular heuristic is to replicate the RQMC process r times (say, about 10) to obtain r independent realizations of the estimator, and use these r observations to compute a confidence interval based on the normal or Student distribution. Alternatives include various types of nonparametric bootstrap methods for which normality assumptions are not required. We report extensive numerical experiments that compare these methods in terms of the width and coverage probability of the confidence intervals, for a variety of examples. The results were not exactly as we expected. Based on these results, we give our recommendations.

2 - Bootstrap approach to quantifying uncertainty in index tracking and enhanced indexation

Hakim Mezali

The focus of this paper is on demonstrating the creation of portfolio uncertainty bands using a bootstrapped procedure. We restrict attention to the model presented in Mezali and Beasley [1] and use re-sampling statistical techniques to build in-sample portfolio uncertainty bands. Further, we propose a number of ways in which the in-sample bootstrapped portfolios, which collectively form an uncertainty band, can be employed to improve out-of-sample portfolio performance for both index tracking and enhanced indexation. Our formulation includes transaction costs, a constraint limiting the number of stocks that can be in the portfolio and a limit on the total transaction cost that can be incurred. Numeric results are presented for eight test problems drawn from major world markets, where the largest of these test problems involves over 2000 stocks. Keywords: enhanced indexation; index tracking; portfolio optimisation; quantile regression; bootstrapping

3 - Classification in a vector space with the infinity norm

Seán McGarraghy, Milena Venkova

Zhou and Schoelkopf (2005) note that "Many real-world machine learning problems are situated on finite discrete sets. Typically we may assume that there exist pairwise relationships among data." In this talk we consider the general setting of classification on data sets in finite metric spaces: these include a broad range of cases, including pairwise relationships satisfying the triangle inequality. Instead of embedding the data in an Euclidian space and using kernel techniques, we embed it in a real vector space endowed with the infinity norm. This embedding is necessarily isometric which means that the data in the normed space can be studied without introducing any distortion to the original metric space setting. While the target feature space is no longer an inner product space, and so the idea of kernel does not carry forward, there is still potential for a linear class boundary using the Hahn-Banach Theorem. We discuss the advantages and disadvantages of such an embedding in the context of classifiers such as support vector machines. In particular, we are interested in the problem of adjusting an already-trained binary classifier in response to new data. New training set data may become available after training a support vector machine: will the same trained machine still work or does it need to be adjusted; and if so, how?

Modelling social-behavioural phenomena in creative societies

Stream: Behavioural OR

Invited session

Chair: [Leonidas Sakalauskas](#)

1 - Modeling&Simulation of Social-Behavioral Phenomena in Creative Societies

Leonidas Sakalauskas

Recently, there have been a growing number of challenges related to processes that are taking place thanks to interactions between people (their communities). Society creates a set of social behavioural phenomena (e.g., the conduct of voters during elections; the behaviour of the crowd during a terrorist attack; people's behaviour during pandemics; institutions' social capital development processes; the behaviour of social network users; etc.), whose knowledge of mechanisms is essential for building a sustainable society. We aim to review the operationalisation of such phenomena as the expression of logical and verbal communication in order to develop a paradigm of rational choice for the efficient understanding of their nature and relevant decisionmaking, thus bridging OR with social sciences and humanities. The creation of such a paradigm on the basis of the theory of structural equation modelling (SEM), multi-agent modelling and game theory, together with data science and mathematical sociology methods, allows the development of data-driven operationalisation for evidence-based solutions.

2 - On the gap between data and models in COVID-19 analysis

Vytautas Dulskis, Leonidas Sakalauskas, Rimas Jankunas

A scrutiny analysis of the COVID-19 data is required to get insights into effective strategies for pandemic control. However, a particular gap between official data and methods used to assess the effectiveness of various containment measures (e.g., COVID-19 passports) hinders sound inference-making. Seeking to escape the burden of arising obstacles, employing the principles and methods of descriptive statistics is often tempting, but in-depth analysis demands more sensitive and reliable methods. In this regard, this paper advocates a maximum likelihood compartmental modeling approach, which provides the flexibility to raise various hypotheses about infectivity, recovery, and mortality dynamics and to find the most likely answers given the data. Our paper is based exclusively on COVID-19 deaths in light of official data limitations, as relatively fewer limitations characterize these data. Nevertheless, this paper does not solve the underlying problems but hints at potential improvements in official data reporting that could benefit COVID-19 modeling prospects.

3 - Mobs Simulation Guided by Social Science-Based Multi-Theoretical Framework

Nitin Agarwal, Samer Al-khateeb

Social media sometimes empowers potential adversarial state actors, paid trolls, and extremists to incite hysteria and coordinate nefarious actions, e.g., deviant mobs. A mob is an event organized via social media or other forms of digital communication technologies in which a group of people gathers online and/or offline to conduct an act collectively and then disperses. To an outsider, such an event may seem arbitrary; however, a sophisticated amount of coordination is involved. These mob-like events like the January 6, 2021, U.S. Capitol attack, or GameStop's stock "flashmob investing" are becoming widespread due to the affordability of social media, ease of use, effectiveness of individuals or groups in conducting coordinated acts, anonymity of the internet, etc. The prevalence of these incidents underscores the inadequacy of current systems (security, financial, etc.) in addressing such coordinated behavior. This topic is understudied due to lack of data, theoretical underpinning, and computational resources required to analyze the complex and dynamic social processes among mobbers. In this study, we develop a model that can simulate mobs guided by constructs extracted from various social science theories. We then aim to use the model to study the behavior of the mobbers, the motivation of the organizers, and attempt to infer the mob's outcome. Real-world data, albeit limited, will be used to evaluate the simulation-driven model in a real-world setting.

4 - How Blockchain and Smart Contracts Transform Human-Machine Trust and Inter-Organizational Relationships in Industry

Yan Peng, Dan Ke

This research systematically examines the impacts of blockchain and smart contracts on human-machine trust, and thus to understand how these cutting-edge technologies and innovative applications are poised to revolutionize industrial inter-organizational relationships and business collaborations. The research model reveals that how blockchain and smart contracts enhance the reliability and efficiency of transactions, thereby fostering a new level of trust between humans and machines. We hypothesize that the immutable and transparent nature of blockchain, coupled with the autonomous execution of smart contracts, streamlines processes, reduces disputes, and facilitates seamless inter-organizational collaborations; the token economy fostered by blockchain and consensus mechanism plays a moderating role by incentivizing organizational behaviors and creating value within the ecosystems by redefining business models and revenue streams. The study adopts a mixed-methods approach. The qualitative interviews from experts and practitioners delve into transformation in trust dynamics and collaborations models enabled by blockchain technology, and the quantitative analysis of data collected from blockchain-implemented systems in industry focuses performance metrics and trust indicators pre & post blockchain implementation. This research

provides a comprehensive understanding of the transformative potential of blockchain and smart contracts in reshaping industrial landscapes.

AI in Knowledge, Technology, and Innovation

Stream: Knowledge, Technology, and Innovation

Invited session

Chair: *A. D. Amar*

Chair: *Nikos Karacapilidis*

1 - Leveraging Open Innovation Practices Through Emerging Technologies

Nikos Karacapilidis, Stavros Dimopoulos, Konstantinos Konstantinopoulos

This paper reports on a novel software platform that aims to facilitate and enhance diverse open innovation practices in contemporary organizations. The proposed solution builds on and advances a series of state-of-the-art artificial intelligence and natural language processing tools and technologies to meaningfully cluster and aggregate stakeholders' feedback. In addition, it adopts an argumentation-based collaboration approach to augment knowledge reification and co-creation. Through dedicated services, the platform augments knowledge management and informed decision-making in the associated data-intensive and cognitively complex settings. The proposed solution has been shaped through long collaboration among diverse types of stakeholders, through which a series of rich application scenarios have been designed and analyzed. Evaluation results are positive, justifying the rationale of our approach towards integrating machine reasoning features that can automatically organize, analyze and summarize the content of ideas and positions expressed in the settings under consideration.

2 - Innovation, Technology, and Entrepreneurship Low Development: a Literature Review based Multi-level and Network Density Analysis.

Homero Malagon, Aida Huerta-Barrientos

Mexico like other developing countries has been battling low outcomes in innovation, technology, and entrepreneurship projects and policies, to understand that phenomenon a multi-level and network density analyses based on a literature review of innovation systems models, in order to analyze how many levels and agents are interacting in these models as well as the relationships between agents. The innovation systems analyzed are the National Innovation System, Regional Innovation System, Triple Helix, Quintuple Helix, Innovation Ecosystem, Entrepreneurship Ecosystem, National Innovation Ecosystem, and Regional Innovation Ecosystem. The results show that for all models only two levels are operating, one government level and the institutional level, and therefore not all levels are articulated; the number of agents considered by each model is relevant but not determinant of the model's quality; network density better reflects the conceptualization of each model; Entrepreneurship and Innovation Ecosystems models have higher network density, and therefore are the recommended ones to be used by planners, strategists, and decision-makers in order to obtain better outcomes; the most likely path to follow by the innovation systems literature and researchers is complex adaptive systems.

3 - Analysis of digital innovation configuration effect on supply chain resilience[U+FF1A]case of logistics firms

Xinbing Gu, Hing Kai Chan

The operation and services of logistics companies can be heavily disrupted due to disasters and crises, requiring them to be more resilient. Digitisation innovation has advanced considerably in the last decade and motivated supply chain resilience (SCR). Given the high level of

socialised services and strong conductivity and linkage roles of logistics firms, the impact of any supply chain disruptive events on the logistics industry will be transmitted and significantly affect the production and operation of upstream and downstream enterprises such as manufacturing and retailer companies. However, it is still unclear how logistics firms systematically facilitated SCR by digital innovation. This study identifies digital innovation as exploratory and exploitative digital innovation. Combined with factors of resourcefulness and dynamic capability, this study applied Fuzzy-set Qualitative Comparative Analysis (fsQCA) and Artificial Neural Network to analyse the digital innovation configuration effect on supply chain resilience. Data from 167 logistics firms reveals three digital innovation model designs, each with its performance implications. Moreover, this study found that exploratory digital innovation is the core condition for motivating SCR. It provides researchers with a new line of inquiry and strategy suggestions on the role of digital innovation in SCR.

Hydrogen and Electricity Modeling and Regulation II

Stream: Energy Markets
Invited session

Chair: *Jens Weibezahn*
Chair: *Lissy Langer*

1 - Important features when modeling hydrogen as part of integrated energy systems

Marie Münster, Rasmus Bramstoft, Dimitrios Eleftheriou, Kenneth Karlsson, Mathias Kjærgård Hald, Magdalena Komoszynska, Henrik Lund

Recently, a number of energy system analyses have emerged, which highlight the potential roles of hydrogen in future energy systems. The results however differ substantially in terms of the outcomes. This is partly due to hydrogen being an expensive energy carrier, which requires a number of conditions to become feasible in large scale some of which include e.g. high carbon taxes, the availability of low-cost renewable electricity and low availability of biomass. To investigate in more detail where the differences stem from, a number of studies of the role of hydrogen in Denmark has been compared and a modeling and reporting framework is proposed. The goal of the framework is to ensure transparency and understanding of results highlighting important input parameters and conditions. The 7 main features identified can be summarized as: 1. Model type 2. Modeling of time (aggregation, pathways and foresight etc.) 3. Modeling of space (aggregation, scope, grids etc.) 4. Scenario boundary conditions (e.g. CO₂ tax/cap, import/export possibility etc.) 5. Resource assumptions (potentials, prices, variance etc.) 6. Technology assumptions (conversion, storages etc.) 7. Demands (energy carriers, sectors included, amounts & timing & flexibility etc.) In order to be able to compare and understand differences between different studies it is recommended to document and reflect upon these model characteristics as well as the main assumptions and modeling choices.

2 - What Could Go Wrong? Disrupting Denmark's Energy Transition Using Policy-Driven Scenarios

Frederik Fristed

In the run-up to 2030, the path towards the EU's ambitious 55% CO₂ reduction goal is shaped by existing energy infrastructure and already adopted policies. Each nation's energy system characteristics, reduction targets, and local challenges affect the EU's collective decarbonization. This work utilizes the open PyPSA-Eur model for the sector-coupled European energy system, comprising 33 countries and Denmark with a higher resolution of nine nodes. The study examines

Denmark's green transition and how it could be disrupted when different sectors fail to meet set targets for decarbonizing agriculture and expanding capacity for green hydrogen electrolysis, renewable generators, and power-to-heat. We constrain CO₂ emissions on a national level, aligned with each country's pledged CO₂ reduction targets, and, in Denmark, implement frozen-policy projections for energy production and sectoral emissions. Focused on 2030, we analyze eight scenarios to assess the impact of each sector on system investments and CO₂ abatement costs. In addition, we extend the time horizon to 2040 to account for the increasing decarbonization efforts of neighboring countries. We show: (1) increased CO₂ abatement costs if the agricultural sector fails to decarbonize; (2) the crucial role of heat electrification for low-cost flexibility; (3) the dependency of green hydrogen investments on renewable capacity limits and emission constraints in surrounding countries. Our model and data are openly available.

3 - Conditions on electricity purchasing: More (emission reduction) bang for your buck?

Lissy Langer, Anders Bjørn, Ben Hobbs, Matthew Brander, Rasmus Bramstoft

This paper analyzes the impact of different electricity purchase conditions on the carbon emissions of hydrogen production. These conditions are also discussed in the context of the revision of the Greenhouse Gas Protocol's carbon accounting rules for the purchase of voluntary renewable energy certificates to report companies' scope 2 carbon emissions. The techno-economic analysis presents a case study of hydrogen production in Denmark, a country with a relatively high share of renewable energy sources (RES), comparing the cost-optimal energy system for 2030 with a counterfactual scenario with no electricity purchase conditions. The study analyzes the impact of annual and hourly matching through power purchase agreements (PPAs) with local RES versus purchasing renewable energy certificates (RECs) through virtual PPAs on carbon emissions, system costs, and carbon reduction costs. We compare several European countries with different characteristics, such as varying initial RES shares, grid carbon intensity, and RES potentials. Our initial results suggest that the purchase conditions significantly affect the distribution of RES between countries, the additionality of RES, and the total system emissions.

4 - Three Pillars of Hourly Matching: A Tour From Model Land to Real World

Igor Riepin, Elisabeth Zeyen

Hourly matching—the concept of matching energy demand with clean electricity supply on an hourly basis—has gained immense attention. The concept got into the spotlight when regulations on how to certify hydrogen as "green" (and thus qualify for support schemes) sparked active debates among both the European Union and the United States' policymakers, industry stakeholders, and research communities. Hydrogen regulation is not the only application of the concept. Through hourly Carbon-Free Energy matching (usually called 24/7 CFE), some public and private energy buyers have pledged to eliminate all greenhouse gas emissions associated with their electricity use. The concept of hourly matching is founded on three pillars: temporal alignment, geographical scope, and additionality of clean energy supply. Several research groups have recently developed energy system models to explore the designs and implications of temporal hydrogen regulation and voluntary 24/7 CFE commitments. The resulting studies and models behind these studies consider the three pillars of hourly matching. Our work discusses these core principles of hourly matching and their implementation in models. Using our own research papers and reports as examples, we take a critical look at which modeling choices we make and what their real-world implications are. Our talk aims to bridge the gap between the land of energy models and the real world using the narrow yet crucial lens of hourly matching.

1 - Stochastic patient admission scheduling problem with an exponential number of scenarios

Haichao Liu, Jin-Kao Hao, Yang Wang

Hospital admission management is a fundamental challenge due to the uncertain demand for inpatient beds. This paper studies a stochastic variant of the well-known patient admission scheduling problem, which aims to assign patients to rooms during their hospitalizations while considering the overstay risk. We consider the problem as a two-stage stochastic programming problem where the first stage assigns patients to rooms on their planned hospitalization days, and the second stage evaluates the expected costs resulting from patient overstay. We propose two novel stochastic programming models to formulate the problem, including a scenario-based model and its equivalent state-variable model. The latter has a pseudo-polynomial number of variables and constraints, which is significantly smaller than the former. To solve the state-variable model efficiently, we apply the sample average approximation method to provide an initial feasible solution to the Gurobi solver. We carried out extensive computational experiments to evaluate the performance of the proposed models. The computational results revealed that our state-variable model finds high-quality feasible solutions with an average optimality gap of 3% for benchmark instances with 250 patients and 1.9E119 scenarios in 1 hour.

2 - Data-Driven Robust Scheduling of Elective Patients

Nan Yang, Jingui Xie

Hospital beds are an important medical resource, and the dynamic admission scheduling of elective patients can help to avoid bed shortages. However, such elective patients scheduling problem is challenging due to the high level of uncertainty behind the bed availability and its impact on admission rates. In fact, Meng et al. (2015) proposed a robust optimization approach to determine the elective admission quotas based on budgeted uncertainty sets to minimize the expected bed shortages. A key challenge to be addressed by this approach is the uncertainty behind the stochastic patient arrival and length of stay (LoS). However, the budget of the uncertainty set is not easy to determine, which in contrast can be avoided in the robust satisficing approach proposed by Long et al. (2022). Robust satisficing favors solutions where the risk-aware objective function best achieves an acceptable goal even when the actual probability distribution deviates significantly from the empirical distribution, and it can tolerate greater uncertainty than robust optimization. In this paper, we propose a robust satisficing method for determining quotas for elective admissions, which will best avoid bed shortages under extreme uncertainty. We do numerical experiments for the proposed robust satisficing model based on the MIMIC-IV dataset and compare it with the results generated by robust optimization methods. The results show that the robust satisficing model can withstand greater uncertainty.

3 - Predicting next week's bed census: combining medical expertise with data.

Hayo Bos, Stef Baas, Richard Boucherie, Erwin W. Hans, Gréanne Leefink

Bed census predictions play a key role in hospital capacity management decisions, such as ward dimensioning, staffing decisions, patient-to-bed assignment and the development surgery schedules. Currently, predictions are typically solely based on the doctor's estimate of the Expected Discharge Date (EDD). In this presentation, we propose two probabilistic models to combine the EDD with the LOS distributions retrieved from ERP data. Using the Poisson Binomial distribution and probabilistic convolution, we obtain the full census distribution. We apply our method on real world hospital data, and it turns out to be very accurate.

4 - Optimizing Early Discharge: Trade-Offs between Capacity and Readmissions

Jingui Xie

In this work, we consider the ward capacity management problem with readmissions, where the decision-maker optimizes the elective schedule and early discharge policy, so as to minimize bed shortages. Existing research has shown that early discharge can lead to higher rates of readmission, and longer readmission length-of-stay. This sets up the need to balance the temporal trade-off between the immediate capacity freed up by early discharges and increased readmissions down the road. Such re-entry structure creates challenges when modelling via traditional methods. We appeal to the Pipeline Queues (Bandi and Loke 2018) framework, and propose an optimization model where the early discharge policy is expressed as a state-dependent decision rule. The model has a reformulation, which can be solved as a sequence of convex programs with asymptotically linear constraints. In our numerical study, we identify an intermediate region of the probability of readmissions where time-invariant policies can lead to as much as 77% more shortages. Ignoring the effects of early discharge on readmissions can lead to at least 75% and 150% more bed shortages in time-homogeneous and non-time-homogeneous settings respectively, even against un-optimized elective admissions. Using optimal early discharge strategies without jointly optimizing elective admissions will lead to 20% more shortages.

Heuristics in BOR

Stream: Behavioural OR

Invited session

Chair: Konstantinos Katsikopoulos

1 - Cognitive operations: Models that open the black box and predict our decisions

Konstantinos Katsikopoulos

Improving human behavior requires first understanding it. Can mathematical models help provide such understanding? Yes. Cognitive Operations performs a systematic examination of two main approaches to modeling human decision making: optimization and simple heuristics. The approaches are discussed by focusing on general types of decisions—under risk, under uncertainty, strategic interaction and inventory control—and by drawing on economics, psychology and artificial intelligence. Cognitive Operations is committed to supporting academics and practitioners who seek to select a modeling approach that suits the operational decision at hand. It shows how to build models and employs clear criteria for assessing them. For a model to open the black box it must specify the cognitive processes that lead to the observed decisions. To predict decisions means to fix a model in one context and to test it in another. The comparative assessment of optimization and heuristic models serves scientific pluralism and leads to surprising insights. The studies in Cognitive Operations zoom in on bounded rationality, a field pioneered by Herb Simon, who was a founder of behavioral economics, cognitive psychology as well as artificial intelligence, and sometimes also wear the hat of an operations researcher. They are useful complements to empirical, experiential and conceptual studies of behavioral operations. It is possible to open the black box and predict our decisions.

2 - Not Just Small Samples: Successfully Predicting Revenues With the Ratio Heuristic

Florian Artinger

A key psychological principle underlying intuitive forecasting is the use of ratios. A finding is that heuristics, which operationalize such principles, can only predict well in comparison to more complex models when the training sample is small. Challenging this finding, we build on the bias-variance trade-off to develop three conditions under which a simple heuristic can match or even outperform more complex prediction models. To test these conditions empirically, we investigate revenue predictions using the "ratio heuristic": multiply the quantity—revenue, in our case—observed in the first t time units by a constant to predict the future quantity. On 20 prediction tasks, the results are in line with the hypotheses showing that a smaller sample, a longer observation period, or unpredictable changes over time provide performance advantages for the heuristic such that it can outperform more complex, standard prediction models. Moreover, given sufficiently strong unpredictable changes over time can result in a setting where even a large sample and a short observation period do not provide performance advantages for the more complex forecasting methods. That is, managerial heuristics may hold value for business forecasting even in data-rich settings.

3 - Executing prescriptive psychological heuristics: Compatibility effects in decision support applications

Shashwat M. Pande, K.Nadia Papamichail

In this paper, we examine the effectiveness with which individuals execute prescriptive psychological heuristics in multi-criteria decision-making contexts. Despite growing evidence demonstrating the predictive accuracy of simple psychology-inspired decision-rules, there has been limited research exploring how well individuals deploy an "adaptive toolbox" of methods intended for use as prescriptive decision-aids. Contrasting between compensatory and non-compensatory heuristics, our study provides some of the first experimental evidence indicating that compatibility among individual, model and environmental features facilitates the application of heuristic-methods in multi-criteria decision-making settings. We draw on the neuropsychological, behavioral and decision analytic literatures to derive our experimental framework and contextualise our findings within the broader discourse in Behavioural OR (BOR).

1 - A biography

Thu Huong Dang

My name is Thu Huong Dang, and I am currently a lecturer at Lancaster University.

My doctoral research, which received partial sponsorship from RouteWare, Inc., was concerned with addressing Combinatorial Optimization Problems (COPs) arising in urban waste collection and recycling.

To date, I have authored several papers on Vehicle Routing Problems and Flowshop Scheduling Problems. I am honored to have received the YoungWomen4OR award from the WISDOM forum within EURO and the Kingsman prize from the Management Science department for being recognized as the best doctoral researcher in the period 2022-23.

Now, my primary focus lies in tackling various COPs, where I explore exact methods to achieve proven optimality and heuristic methods for addressing real-world challenges. Over the next few years, I am contemplating expanding my research to include interdisciplinary topics, such as the use of AI/machine learning in addressing COPs.

2 - My (short) research journey: past accomplishments, present projects, and future aspirations

Laura Davila-Pena

Not everyone follows the same path in life, and this is no different in the case of academia. There are those who focus on one topic from the beginning, those who explore many and eventually define themselves, or those who keep exploring. I believe I am one of the latter.

This talk intends to give an overview of my research journey, starting back in 2016 when I first faced Operations Research. I will briefly describe the research I have done so far (vehicle routing, machine learning, cooperative game theory, scheduling, etc.), along with the process and achievements. I will also present my ongoing work and give some insight into the direction I aim to take in the future.

3 - How to "locate" Mathematics in everyday life

Serena Fugaro

At the beginning of my academic career, I was often unable to answer the question "What is the use of mathematics?" convincingly, and as a mathematician, I felt rather frustrated. Then, out of pure curiosity, I took a course in Operational Research during my Master's degree and found the first concrete applications of mathematics to real-world problems. Today, thanks to my engagement in technology transfer alongside research, I could go on and on about the location of mathematics in everyday life. In particular, the word "location" is not accidental: in fact, over the last three years, my research activity has focused on Discrete Facility Location, with the aim of improving decision making in complex scenarios resulting from administrative, managerial and operational needs. Actually, the decisions involved in Facility Location are inherently strategic, and this has led us to define problems characterised by many, potentially conflicting objectives, as this talk will detail. Indeed, we have introduced a novel class of Multi-Objective Covering Location problems and an original Multi-Objective Facility Location problem in Waste Management, arising from a case study for the city of Sheffield. In both cases, we derived ad hoc mathematical formulations and obtained accurate representations or approximations of the arising Pareto Sets. We also conducted a systematic literature review which allowed us to highlight the research gaps in the literature on Multi-Objective Facility Location, and to derive a research agenda to suggest concrete guidelines for both researchers and practitioners interested in this area.

Reducing Food Waste

Stream: Secure & Sustainable Food Supply

Invited session

Chair: *J.c. Gerdessen*

1 - Reduced food waste despite throwing out food before expiration: online vs. offline retail

Ayse Sena Eruguz, Jorrit Barto, Remy Spliet, Sanne Wöhlk

Online retailers throw out food that has not yet expired. This gives rise to the question whether online retailers generate more food waste than offline retailers, who typically throw out food only after it has expired. We focus on the food waste at the retailer which inherently ensues from the logistical set-up. We first provide a theoretical analysis to establish whether throwing out food before expiration indeed results in an increase in food waste, putting online retailers at a disadvantage compared to offline retailers. We show for well-behaved inventory control policies, including the optimal policy, that food waste increases when food is thrown out before expiration. Next, we compare the food waste of the online retailer with that of an offline retailer in numerical experiments. Note that the online retailer has some advantages over offline retailers as well. Online retailers benefit from full

control of order picking, which is instead often done by the consumer in offline retail. Moreover, the online retailer often benefits from the pooling effect, as offline retailers might use multiple stores to satisfy the same demand volume as an online retailer from a single warehouse. Our numerical experiments with a base-stock policy suggests that online retail actually yields less food waste for many products, despite throwing out food before expiration.

2 - Analysis of Markdown Strategies for Perishable Products

Lena Riesenegger, Alexander Hübner

Discounting perishable products before they expire, known as markdown pricing, is today's most common and popular reactive food waste mitigation practice among retailers. Product age and price influence customer behavior: While some customers do not buy products that are about to expire, discounted prices may attract new customers who initially did not plan to buy the product. The time of discounting and the applied discount level are crucial decisions. Early discounts can lead to margin losses, while late discounts may generate too little demand. If the price discount is set too high, the remaining stock may be sold quickly and completely, but the margin may be considerably lower. Current literature lacks consideration of different product ages on the shelf and the corresponding behavioral dynamics of customers. We contribute with a simulation study that considers price elastic demand, customers' freshness preferences, and changes in customer behavior when a discount is applied. We conducted several experiments considering different customer preference patterns. Results show that discounts are particularly worthwhile for products where customers prefer fresh products and withdraw them according to last-expired-first-out. Furthermore, customers switching from fresh to old, discounted products contribute to food waste reduction, while the influence on profit depends on the product's initial waste level.

3 - Menu planning for food services: reducing food waste by the use of leftovers under consideration of demand uncertainty

Marjolein Buisman, Marloes Remijnse, Ahmadreza Marandi, Sonja Rohmer

Food waste levels in the food service sector can be up to 30%, mainly caused by overproduction, as food is produced upfront rather than on demand. Therefore, there is a significant risk of meals or meal components to be left uneaten. Leftover meal components might be used in other dishes; however, due to the short shelf life of these products, time is a limiting factor. Adequate and flexible meal planning might increase the reuse of these leftover products and, therefore, reduce the environmental impact of the food sector. In this study, we propose an innovative menu planning model for the food service sector. The model incorporates the common meal planning decisions on which ingredients to purchase and which meals to offer on a day, but also allows storing excess meal components and using them in the following days. This model aims to provide a menu with the least environmental impact but also aligns with the requirements of the customers and the budgetary constraints of the food service. Using Adjustable Robust Optimization, the model incorporates the uncertainties inherent in food service operations, such as fluctuating customer demand.

4 - Optimizing household food planning: a rolling horizon MILP model for reducing food waste

Maïke van Rooijen, G.D.H. (Frits) Claassen, Sander De Leeuw, J.c. Gerdessen

One-third of the global food production is lost or wasted. Of the total food waste in Europe, about 50% is caused by households. Food waste is the undesired result of multiple household food management behaviors. Food waste prevention behaviors, such as planning, aim to avoid a surplus of food reaching the household. However, the unpredictability of everyday life causes households to deviate from plans. Food recovery behaviors focus on using all the food that has entered the household. Although food prevention interventions have been thoroughly studied, interventions targeting food recovery have not yet received much attention in literature. Food recovery is, among other factors, influenced by household demographics, flexible cooking skills, shopping frequency, and shelf-stable food items on stock. As many of these

factors are interrelated, it is difficult to quantify the effect of individual factors on food waste. Simulations of complex problems have proven helpful to shape interventions. However, they have not yet been used to study food waste. The aim of this study is to develop a meal planning model with a rolling horizon to simulate disruptions that might occur in everyday life with different shopping strategies. This gives insights into best practices regarding food recovery behaviors. The results of this study can be used to shape new interventions to reduce food waste.

Surgery Scheduling and Operating Room Planning (2)

Stream: OR in Health Services (ORAHs)

Invited session

Chair: *Jens Brunner*

1 - Solving three-stage operating room scheduling problems with uncertain surgery durations

Yang Kuei Lin

Most of scheduling problems consider a deterministic environment for which the data are known. However, in many real-world problems, the precise values of data in scheduling models might not know in advance. For example, the precise duration of surgery is hard to predict because it can vary widely from one case to another, even for identical procedures. The post-surgery duration is also hard to predict because it is influenced by the patient's age, gender, condition, type of surgery and type of anesthesia, etc. We consider a three-stage operating room surgery scheduling problem with uncertain surgery and post-surgery durations. The three successive stages are pre-surgery, surgery, and post-surgery. No-wait constraint is considered among the three stages. Surgeries are known in advance (elective). Multiple resources are considered throughout the surgical process: PHU (pre-operative holding unit) beds in the first stage; ORs (operating rooms) in the second stage; and PACU (post-anesthesia care unit) beds in the third stage. The objective is to minimize the makespan. We have proposed a genetic algorithm for robust scheduling (GARS). Randomly generated problem instances are tested to evaluate the performance of the proposed GARS. Computational results show that the robust schedules found by the GARS are relatively insensitive to uncertain surgery durations when compared with the non-robust schedules found by the basic GA (BGA).

2 - Operating Room Scheduling under Human Resource

Xiajie Yi, Christine Di Martinelly

Effective Operating Room (OR) scheduling holds significant financial implications for hospitals, particularly when dealing with inpatient procedures at the operational level. However, the duration of a surgery is often uncertain and it is rather challenging to accurately predict. Estimates can vary significantly across different departments, leading to various extents of underestimations. As a result, it exacerbates nurse shortage issue in hospitals. To address this, we propose an approach to build robust surgery schedules in an OR theatre made of several rooms with different specialties and sharing nurses. Our method utilizes a two-stage stochastic optimization model. In the first stage, we determine the number of nurses working each day, while the second stage focuses on creating the detailed schedule. Additionally, we adopt the sampling average approximation (SAA) technique to address uncertainties in surgery duration. Based on the samples generated from real-life data, the simulation results imply that i) the surgery schedule could be fully scheduled with fewer number of nurses; ii) the nurse shortage/absence issue can be potentially avoided as we can accommodate uncertain duration better.

3 - A two-stage operating room scheduling method for reducing hospital surgical waiting times for elective surgery lists

Victor Riquelme

Chile's public healthcare system covers nearly 80% of the population. Despite its large coverage, it is characterized by long waiting times of its waiting lists. Our objective is to efficiently schedule hospital operating rooms for elective surgeries, to reduce the mean and median waiting time of the surgical waiting list. Our case study corresponds to a high complexity public pediatric hospital in Santiago, Chile. The hospital works based on morning and afternoon time blocks, each to be allocated to a single specialty for each operating room. Overtime is only allowed for long surgeries.

For a given planning horizon, our strategy consists of two stages. First, we assign the medical specialties to the operating rooms, days, and blocks, by solving an integer linear programming problem that balances the available time in the planning horizon with the required surgery time demanded by each specialty. This considers variables such as the number of hours per block and the availability of surgeons per specialty and day. Second, we assign patients to the blocks based on one or more efficiency metrics. For instance, if only waiting time is considered, priority is given to patients with longer waiting times.

The proposed scheduling model, although suboptimal, is faster than classical single-stage integer linear programming approaches, and shows more flexibility, as patients can be rescheduled without the need to rerun the scheduling once specialties are assigned to blocks.

4 - Integrated surgery and staff scheduling using column generation

Jens Brunner, Stefanie Ebel

Physicians and operating rooms are two of hospitals' most important, expensive, and scarce resources. Therefore, effective and efficient scheduling of these resources is among hospitals' most relevant planning tasks. The decisions to be made on the daily planning level regarding sequencing patients' surgeries and assigning appropriate staff to surgeries. Since there are several interdependencies between surgery schedules and physician rosters, it is a meaningful approach to consider both planning problems within one integrated optimization problem. We provide mixed-integer programming models within a column generation algorithm that solves both scheduling problems. We create schedules for surgeries and operating room staff. We use test data based on a real-world dataset to provide meaningful insights. The algorithm leads to optimal solutions in more than 75% of all test cases and solves the problem efficiently within a desirable amount of time. We further evaluate our algorithm with respect to different aspects of flexibility in the context of surgery and staff scheduling and generate key insights about their interdependencies.

Developing Countries and Sustainable Humanitarianism

Stream: OR for Development and Developing Countries
Invited session

Chair: *Nina Kajiji*

Chair: *Gordon Dash*

Chair: *Milagros Baldemor*

1 - Exploring subscription-based online services (SOS) for sustainable businesses of indigenous cottage products: a behavioural study on cottage textile subscription via SEM

Shivam Singh, Nomesh Bolia

SOS is an e-commerce format that is getting popular across many products like apparel, food, medicine, baby care, cosmetics, and more. Many brick-and-mortar firms are adopting SOS as their revenue model. SOS can efficiently provide sustainable revenue to industries facing economic sustainability issues, like the cottage industry, and help contribute to SDG 8. However, it is crucial to analyse customer's intention to subscribe to any SOS. Thus, using the structural equation modelling method, this study analyses factors related to consumer attitude, motives, and barriers affecting the intention to subscribe (ITS) to hand-crafted textiles that face sustainable revenue issues. This study is novel as the variables include product consumption and subscription viewpoint. Multiple theories from the literature support the model, which improves the model's generalizability. Results show that consumers' attitudes and motives towards consumption and subscription positively affect ITS. In contrast, perceived risks, market and consumption barriers negatively affect ITS. This work finds availability and cost issues as significant obstacles to cottage textile consumption. SOS's doorstep availability and reasonable price attributes can shift such consumers towards availing cottage textile subscriptions. SOS retailing thus indicates a positive market outlook. The results are checked for demographic and psychographic group differences that enhance the market implications of this study.

2 - Understanding donation patterns in the immediate aftermath of sudden onset disasters

Can Erzi, Raha Akhavan-Tabatabaei, Nezh Altay

The question of why and how humans choose to help others without expecting anything in return has puzzled philosophers, psychologists, and economists for centuries. This becomes even more important during Sudden Onset Disasters (SOD), where understanding donor behavior plays a critical role in efficient management of Humanitarian Supply Chains. Demographics, trust, and personal history all have an impact on the individual's donation decisions. Another factor is the perceived closeness to the victims. "Psychic Distance" (PD), a concept borrowed from international business literature, is adapted to describe donor-victim relationship in terms of shared personal history and cultural closeness. We propose another dimension to the PD under SOD conditions: donors' temporary mental, physiological and financial states. Since decisions during SODs are taken within a short time frame, we expect these contextual factors to play a significant role in the donation decisions as well. Through conducting an experimental design, we study donation decisions of the subjects while their psychology and physiology are manipulated via different priming methods. The objective is to observe changes in intention to donate, and donation preferences, while the perceived contextual PD is modified.

3 - Role of perceived over qualification and job crafting in mitigating cyberloafing: A moderated-mediation model

Nivedita Jha

This research aims to develop and evaluate a model that explores the relationship between perceived overqualification, job crafting and employee cyberloafing. Drawing on job-demand resource theory, the model proposes that employee engagement serve as an explanatory factor in this association. Additionally, it has been suggested that the ambidextrous leaders also positively impact employee engagement which in turn reduce cyberloafing.

4 - The Role of Ethics and Altruism: Mapping the Determinants of Healthcare Accessibility for Medicare Beneficiaries

Nina Kajiji, Gordon Dash, Miriam Dash

It is widely acknowledged that healthcare providers' interests may diverge from those of patients. In and of itself, healthcare accessibility is a complex measure rooted in the ability of an individual to receive healthcare effectively with demonstrated anxiolytic effects. Annually, the Center for Medicare and Medicaid Services gathers survey data from current beneficiaries of Medicare in the United States and Puerto Rico (excluding healthcare facilities) to assess healthcare equity. These surveys delve into chronic risk factors associated with various diseases and mental health conditions. This study innovates extant Medicare patient care models by identifying the error-minimizing determinants underlying the probability of delivering a correct chronic condition diagnosis. We propose a novel multiobjective and multi-target shallow-learning radial basis function artificial neural network specification for

classification. Using Explainable AI, we provide policy-based results, allowing providers to understand Medicare patients' disease pathology better. Diagnosticians are likely to have a lesser financial incentive to recommend profitable procedures regardless of appropriateness, reducing poor quality and costly care when providers are profit-incentivized instead of generous.

OR in Energy III

Stream: OR in Energy
Invited session

Chair: Sicheng Gong

1 - Coordinated Medium- and Low-voltage Distribution Systems Planning Under Volatile Energy Sources Deployment

Alfredo Ernesto Oneto, Blazhe Gjorgiev, Giovanni Sansavini

Efforts to mitigate emissions have led to the introduction of more distributed and volatile generation, such as photovoltaics, along with flexible and smart loads. This shift strains the reliability of power distribution systems (PDSs), which are expected to adapt to these challenges. Volatile energy sources further affect the interaction between medium-voltage (MV) and low-voltage (LV) levels in PDSs. Hence, distribution system operators need novel strategies for efficient capacity enhancements.

The distribution expansion planning (DEP) problem seeks optimal PDS design, minimizing investment and operational costs while meeting service requirements. Existing literature on DEP often overlooks the interplay between LV and MV systems. However, isolated investment plans may not remain optimal (or even feasible) for integrated MV/LV systems, necessitating coordinated models. This work addresses the gap by exploring coordinated DEP for MV and LV systems with volatile energy sources.

We leverage spatial aggregation techniques for large-scale planning. To evaluate the proposed approach, we utilize representative PDSs in Switzerland. This research enhances the adaptability and efficiency of modern PDSs amidst the increasing deployment of distributed and volatile energy sources.

2 - Robust Optimization for Long-term Uncertainty in DER Sizing and Placement in Distribution Networks

Fernando García, Sebastián Dávila, Franco Quezada, Cristian Duran Mateluna

This study comprehensively compares stochastic programming and robust optimization approaches for handling long-term uncertainty in the optimal sizing and placement of distributed energy resources (DERs) in LV distribution networks. The study covers various optimization models, ranging from a deterministic model to a two-stage stochastic programming approach, single-stage robust optimization, adaptive robust optimization (ARO), and a hybrid variant of stochastic robust optimization, considering the electricity load and power generated by PV systems as random variables. A decomposition method approach has been used to address the three levels raised by robust optimization using primal and dual cuts. The models have been tested using a modified version of the IEEE 33 bus system, comparing mainly the ARO with the hybrid models because the hybrid model allows the handling of PV generation through a stochastic approach and the electricity demand by a robust method, which could be more suitable to represent their uncertainty in long-term scenarios. Thus, the results show that the hybrid approach i) reduces the convergences times, ii) reduces around 80% on average the number of iterations regarding the ARO for different Budget of Uncertainty (BoU) levels, and iii) delivers a notably less conservative solution than the ARO.

3 - Optimal Integration of Microgrids in Smart Grids During Cold-Load Pick-Up

Levan Pavlenishvili, Miguel Anjos

Renewable energy generation in microgrids can have an important role in the decarbonization of electricity networks. Microgrids can also provide ancillary services to the main grid during different operational circumstances. This paper explores the use of microgrids during cold-load pickup (CLPU) phenomena, which are typical after an outage in distribution networks with high share of thermostatically controlled load (TCL). As load loses diversity after an outage CLPU phenomena is a drastic increase after re-connection. We present a mixed-integer linear programming (MILP) formulation for scheduling service restoration (SR). The proposed model computes the optimal re-connection sequence, generation and storage levels for the microgrids as well as power supply level from the main grid. Unlike existing literature this paper uses a network with multiple microgrids. It also allows for different conditions at the microgrids: with some operating in islanded mode and having diversified load, while others being in outage and having to do service restoration with CLPU. The model is tested on different modifications of the IEEE-13 feeder network. The proposed approach is suitable for practical SR scheduling and to test the CLPU capabilities of a distribution network during the planning process. The model formulation has the flexibility to allow for additional improvements in precision and complexity in estimating its key components.

4 - Geometric Programming for Optimal Hosting Capacity Allocation in Distribution Grids

Sicheng Gong, Koen Kok, Sjeff Cobben

The hosting capacity determines the operational threshold for each integrated energy unit. During hosting capacity allocation, mixed load/generation profiles and intrinsic non-convex network models pose significant computational challenges. This paper introduces an alternative approach for optimal capacity allocation, drawing inspiration from constraint conversion and geometric programming. This approach promises to achieve superior computational speed and a high-quality optimal solution. By initially assessing the multidimensional operational feasible region for involved units, the model simplifies by excluding voltage and current variables, thus reducing complexity. Through model reformulation guided by geometric programming, the model convexity will be established, thus further improving both the speed and solution quality of this solving process. Relevant case studies reveal that the computation time could be reduced at most by 88.3% by adopting the proposed approach. Due to model convexity, even a higher-quality solution can be achieved accordingly, which yields a better objective function value compared to that using the Gurobi benchmark solver. These findings underscore the potential of this approach on computation performance enhancement when determining optimal hosting capacity allocation in electricity networks.

Empowering Energy Access

Stream: Energy Management
Invited session

Chair: Ayse Selin Kocaman

1 - A Strategic Framework for Maximizing Utilization of Minigrids in India: Achieving Financial Sustainability and Productive Energy Integration

Madhav Sharma, Anoop Singh

Ensuring affordable and reliable access to energy in rural communities remains a critical challenge for achieving Sustainable Development Goal 7 (SDG7). Minigrids (MGs) powered by renewable energy (RE) sources offer a potential solution, but their long-term financial sustainability remains a hurdle. This paper proposes a novel approach employing strategic optimization to enhance MG financial viability

through the integration of productive use of energy (PUE). The framework meticulously sizes MGs and generation technologies (solar PV, biomass, etc.) to align with varying seasonal consumer demands. This optimization approach aims to match periods of low-capacity utilization with peak energy processing activities, consequently reducing the leveled cost of electricity (LCOE) for MG users. The benefits are twofold: increased capacity utilization and reduced operational costs, leading to significantly lower consumer tariffs. Through a comprehensive case study, this research demonstrates the effectiveness of strategic optimization in meeting energy needs while ensuring the long-term financial viability of MGs. Notably, the findings emphasize the critical role of improved capacity utilization in fostering MG financial sustainability. This research offers valuable insights for policymakers, practitioners, and stakeholders in the RE sector, demonstrating the potential of optimally designed MGs to drive lasting positive change in rural communities.

2 - Bridging the gap: multi-stage optimization for electricity access

Gözde Yazıcı, Oya Ekin-Karasan, Ayse Selin Kocaman

Approximately 10% of the global population lacks access to electricity, with a significant portion residing in rural areas, underscoring the importance of rural electrification efforts. In this study, we focus on determining the optimal technology choice and network design for rural electrification at macro level. To this end, we propose a series of MILP models that minimize costs by strategically allocating settlements to off-grid, grid, or mini-grid options. Furthermore, we introduce multi-stage versions of these models to guide optimal investment decisions over time, addressing the practical challenge of roll-out electrification plans. Through real-life and synthetic instances, we demonstrate the potential cost advantages of our proposed enhancements.

3 - Hydrogen Refueling Station Allocation Problem: A Case Study for İstanbul

Saliha Büşra Gündüz, Ebru Geçici, Mehmet Güray Güler

Researchers and countries are turning to alternative energy sources as the existing energy sources are insufficient to meet the demand. Hydrogen energy is one of the alternative energy sources and one of its main potential contributions will be through the Hydrogen Fuel Cell Vehicles (HFCVs). To ensure the widespread use of HFCVs, hydrogen fuel must be easily accessible. The number and location of hydrogen refueling stations (HRSs), therefore, have a crucial role for the usage of the hydrogen energy via HFCVs. The subject of this study is to determine of the number and locations of HRSs for İstanbul, Türkiye's most crowded city. The adaptation to hydrogen technology for each district is modelled using a measure for life quality called human development index which is then used to determine the HFCVs' demand based on traffic flow data. We employ three different approaches for modeling the problem in a multi period setting: p-median model, a set covering model, and a hybrid model of both. It turns out that ignoring the transition of adopting hydrogen technology may result in a significant loss. Moreover, instead of spreading from the center to the city boundary, the stations appear at both low populated and high populated regions from early periods of the 30 years planning horizon. Finally, very few numbers of HRSs are sufficient to meet high demand, but the number increases significantly if all demand should be satisfied.

4 - A facility location-allocation problem for rural electrification

Ayşe Selin Kocaman, Beste Akbas

One major impediment to developing countries' economic growth is the lack of access to affordable, sustainable, and reliable modern energy systems. Even today, hundreds of millions of people live in rural areas and do not have access to essential electricity services. In this study, we present a planar facility location-allocation problem for planning decentralized energy systems in rural development. We consider nano-grid and micro-grid systems to electrify rural households. While micro-grids serve multiple households with a common generation facility, nano-grids are small-scale systems serving individual consumers. The households served by micro-grids are connected to the generation facilities with low-voltage cables, for which we employ a distance limit constraint due to technical concerns, including power

loss and allowable voltage levels. For this problem, we provide mixed-integer quadratically constrained problem formulations and propose model-based and clustering-based heuristic approaches.

Information sharing in sustainable supply chains

Stream: Circular Economy, Remanufacturing and Recycling

Invited session

Chair: Christos Papanagnou

1 - Impact of Information Availability in Processing Unsolicited Donations

Adhurim Imeri, Gerald Reiner

Unsolicited in-kind donations, such as textiles, pose significant challenges to humanitarian organisations (HOs) due to the uncertainty of donor supply in terms of quantity and quality of items. To enable flexible operations, HOs deploy donation containers in urban areas. These are processed and the items which they collect are sold as second-hand textiles in retail outlets. However, labour-intensive processing, sorting and waste make it difficult for HOs to sell all donations through retail outlets. Instead, a portion is exported in bulk without sorting to reduce costs. This paper presents a simulation model to understand the processes behind unsolicited textile donations. The results show that the critical process factors are the interplay between local demand for used clothing, the holding costs of storage, and the proportion of waste in donations. The challenge is to avoid shortages in emergency situations without incurring additional storage or disposal costs. In this context, the paper uses an allocation problem to prioritise the sorting of donation containers. This would be facilitated by a platform that processes donor information before the items are dumped in the containers. Understanding sorting processes and donor behaviour is essential to optimise the impact of unsolicited donations on HOs. This study derives actionable implications for such operations and the critical role of donor education in reducing wasteful donations. It also highlights the need for policy

2 - Mitigating the bullwhip effect on supply chains with multiple retailers by horizontal information sharing

Martin Hrusovsky, Emel Arıkan, Lena Silbermayr

Bullwhip effect describes the increasing magnitude of fluctuations in orders in the upstream direction within supply chains that lack proper coordination due to various reasons. One of them is incomplete information sharing about demands, orders or inventory levels, which is caused by the reluctance of supply chain actors to share sensitive information that might increase their vulnerability in negotiations or leak to other actors, e.g. competitors. As a consequence, full information sharing is very often not applied in practice despite its positive effects confirmed by a vast amount of research papers.

As an alternative, we propose to use cryptographic methods, such as secure multi-party computation or homomorphic encryption, that enable to share necessary information (e.g. a certain demand signal or trend) without revealing the exact values of each individual partner. We implement this approach on a 4-stage supply chain with multiple retailers using order-up-to policy where the information about average market demand is shared horizontally between the retailers. In our test we consider factors such as demand variation, correlation of demand or number of retailers sharing the information between each other and we show the positive effect that this information sharing has on mitigating the bullwhip effect.

3 - Benefits of Vendor-Managed Inventory Strategies for the Reverse Logistics Operations in Closed-Loop Supply Chains

Vivien Schoepf, Arne Strauss

As closed-loop supply chains (CLSCs) are gaining importance in many industries as key enablers of reduced waste and ecological footprint, new challenges arise in the integration of forward and reverse logistic flows. This research focuses on a variation of the production inventory problem with open routes and explores the benefits of vendor-managed inventory (VMI) systems for the reverse logistics operations of reusable transport items (RTIs). A stochastic two-stage program considering uncertainty of return flows is developed and solved under use of sample average approximation (SAA) and relaxation-based bounds. We find that the benefits of vendor-managed inventory strategies are not only linked to lower operational cost but also lower stock-out risk in long-term planning. Further, in hybrid networks of partially VMI and non-VMI nodes, the strategic choice for which nodes to implement VMI can positively impact the network performance. This application of VMI in reverse logistics has been scarcely explored in the field and provides new managerial insights for practitioners in the industry.

4 - Probabilistic Control for Reducing the Bullwhip Effect in Recycling-Enhanced Supply Chains

Christos Papanagnou, Randa Herzallah

This study introduces a decision-making methodology employing probabilistic control to reduce the bullwhip effect within recycling-inclusive closed-loop supply chains. Replenishment policies are refined to incorporate recycling operations, and probabilistic controllers are utilised to manage inventory and information flow dynamics. We construct a state space model that encompasses inventory levels, information flow, and recycling activities, capturing their complex interrelations. This model is analysed under stationary conditions, with stochastic customer demand characterised using conditional probability density functions, providing insights into supply chain behaviours.

We explore the characteristics of the bullwhip effect and assess the overall stability of the supply chain. Simulations are conducted to evaluate the effectiveness of our probabilistic control strategy in managing and stabilising the supply chain during such disturbances. The ultimate goal is to enhance supply chain efficiency and resilience in the face of uncertainties through this innovative control approach.

Invited session

Chair: *Xiang Zhu*

1 - Circular economy application in pharmaceutical supply chains in the UK: a holistic evolutionary game approach

Nazanin Nami, Grigory Pishchulov, Joao Quariguasi Frota Neto

The environmental hazards of improperly managed waste have gained universal recognition among scholars and stakeholders. These hazards are especially critical in the pharmaceutical sector as leftover medications contain active chemicals that threaten the environment and human health. Nonetheless, implementation of adequate measures to ensure proper collection and treatment of pharmaceutical leftovers remains insufficient, and tons of unwanted medications are discarded in landfills and wastewater annually. This is due to lack of coordination between the parties and poor incentive systems. To address this issue,

we study coordination in pharmaceutical reverse supply chains and government incentive strategies. We employ the evolutionary game methodology to evaluate strategic behaviour of pharmacies, a recycler, and the government under four incentive plans. We compare the incentive plans based on return volume, participation rate, cost, and implementation time, to recommend the most effective plan. We conduct a numerical study to gain insights into the performance of the incentive plans in different conditions. The results reveal that a plan that provides proper incentives to pharmacies for targeting both, reward- and awareness-driven customers, coupled with contract-based coordination, outperforms other plans, and does not necessarily require a budget allocation. Our study is based on the UK's National Health System but it is generalisable to other countries as well.

2 - Demand response control of wind-based electrolyzed oxygen for advanced activate sludge wastewater treatment

Qipeng Liu, Yi Zheng, You Shi, Krist V.Gernaey

Green hydrogen has been regarded as a promising substance for sustainable energy conversion and storage. However, the by-product pure oxygen, from water electrolysis, has not yet been widely utilized. Meanwhile, the municipal wastewater treatment system is facing great challenges to upgrade its original capacity and the advanced tertiary treatment. This work proposes to integrate electrolyzed oxygen with activated sludge aeration and effluent post-oxidation. An on-site wind/multi-electrolysers' water electrolysis/oxygen model is simulated to satisfy the potential oxygen demands from the Benchmark Simulation Model No.2 (BSM2). The oxygen productivity fluctuates because of the uncertainty from intermittent wind energy; meanwhile, the oxygen demands of aeration and effluent oxidation are also non-linear dynamic variables. The imbalance of day-ahead supply and demands of oxygen is solved by a virtual oxygen storage unit in the model. The optimization goal is to: maximize the real-time oxygen applications of aeration or effluent oxidation; minimize the volume requirements, and usage counts of oxygen storage units. To simplify the simulation system by making the oxygen production and demands deterministic, the short-term forecasting intelligence of linear regression (LR) algorithm is employed. Then the LR is incorporated with reinforcement learning (RL) for scheduling flexible control of oxygen dispatches, so as to make wastewater treatment processes more efficient and accurate.

3 - Optimizing Carbon Capture, Utilization, and Storage Strategy: A Cap-and-Trade Integrated Approach for Power Companies

Xiang Zhu

In pursuit of carbon peaking and carbon neutrality goals, this conference presentation introduces a comprehensive approach: the integration of the "carbon capture, utilization, and storage" (CCUS) strategy with the "cap and trade" principle. Addressing the challenge of securing commitments for both carbon capture and investment within the power sector, our proposed model incorporates linear CO₂ storage, emissions allowance deposit, stochastic CO₂ utilization demand, mean-reverting Lévy jump allowance price process, and a stochastic CO₂ generation process during production. We present the derived optimal commitment policy, considering constraints such as physical carbon storage limitations and rational allowance deposit considerations. Through impact analysis, we demonstrate that our optimal policy allows companies to dynamically adjust investment levels to mitigate risks arising from uncertainties in CO₂ generation and utilization demand. Specifically, under the cap and trade principle, companies can flexibly adapt to cover excess emissions or capitalize on remaining allowance deposits, thus enhancing profitability after achieving the optimal CO₂ capture level under the CCUS strategy. This framework not only contributes to meeting environmental objectives but also provides a strategic and adaptive approach for power companies to navigate the complexities of carbon management.

1 - Online Exploration of Rectilinear Polygons by Multiple Searchers

Taro Abe, Yuya Higashikawa, Shuichi Miyazaki

We consider a problem faced by multiple searchers that have to explore an unknown simple polygon P . At the beginning of the exploration, all the searcher are located at some point inside P , called the origin, and the exploration finishes when any point on the boundary of P is seen by at least one searcher and all the searchers return to the origin. The cost of the exploration is the time needed to finish the exploration, and the objective of the problem is to minimize it. We consider an online exploration, where the searchers create a map of P during the exploration and use it to decide which direction to move.

In this paper, we consider a restricted class of simple rectilinear polygons, which can be created by, starting from the root rectangle, recursively attaching a base of a new rectangle to a lateral side of some rectangle constituting the current object. We present an online exploration algorithm for this class of polygons, and show an upper bound on its competitive ratio that is sublinear in the number of searchers.

2 - The Robust Diversity Difference Problem

Martin Frohn, Kerry Manson

A phylogeny is an edge-weighted binary tree with leaves labeled by a collection of species that represents the evolutionary relationships between the species. Given a phylogeny, a popular measure for the biodiversity of a subset of the species is the phylogenetic diversity, defined by the sum of the edge weights in a minimal spanning subtree of the phylogeny leaf-labelled by the subset. However, if we want to make conservation efforts for particular species, then we consider a phylogenetic diversity index, a function that apportions the biodiversity of a subset across all of its species. In general, for a fixed subset of species, the difference between the phylogenetic diversity and the sum of phylogenetic diversity indices is a non-negative function, called the diversity difference. We study the combinatorics of phylogenetic diversity indices and show that the maximum robust diversity difference for a fixed number of species can be calculated in polynomial time. Furthermore, we provide computational evidence to compare the quality of the optimal robust diversity difference index with other popular phylogenetic indices from the literature in practice.

3 - Computing the effect of multiple cost changes in combinatorial problems

Marcel Turkensteen, Gerold Jäger

In this presentation, we consider sensitivity analysis to combinatorial optimization problems (or binary programming problems). In these problems, there is a ground set of elements, each of them with a given cost. The objective is to find a feasible combination of elements which, in our case, minimizes a total objective value. Sensitivity analysis concerns finding the range of changes in cost values such that current solutions remain optimal. The supremum decrease and increase in a single element's cost, the lower and upper tolerances, respectively, can be computed by solving an additional instance of the problem. When k element costs increase or decrease simultaneously, there is a k -dimensional area in which solutions remain optimal. Jäger et al. (2018, 2023) introduce set tolerances as the infimum and supremum sum of cost changes that lie inside and outside that area. For problems with sum objective, it requires solving an exponential number (in k) of instances to optimality to describe the area (Andersen et al, 2023) and to compute set tolerances. We present new results which show that set tolerances of problems with a bottleneck objective (the objective value

is the largest cost of the elements in a solution) require the solution of only one problem instance. We also show that tolerance computations can be independent of the choice of optimal solution.

4 - On the optimal ranking maximizing a median rank correlation coefficient

Johan Springael

With the abundant availability of data, the importance of proper clustering algorithms has been growing over the past decades. This is even more the case when the objects to be clustered can be represent by either total or partial rankings. A well-known clustering method is the so called k -medoid algorithm. Still the major question remains how to define the median object of a cluster and what is the best one? The similarity measure to adopt in the clustering algorithm when comparing rankings is Kendall's rank correlation coefficient. Here we investigate the subproblem of maximizing the median of a set of rank correlation coefficients so as to determine the best median ranking by determining the optimal ranking. Since the optimal median ranking has to be determined, the rank correlation coefficients will also be variable. Hence, the sorting of Kendall's tau's in order to determine the median in the optimization model should be incorporated. In case tied rank values are absent, we will show that this optimization problem can be re-written as a linear mathematical program. If however ties are present, the linearization will only be possible if the different possible partitions of the rank values are preprocessed.

Chair: Dang Viet Anh Nguyen

1 - Two-stage Time Minimizing Bulk Transportation Problem

Prabhjot Kaur, Meenakshi Mittal

This paper discusses a two-stage bulk transportation problem and develops a polynomial bound iterative algorithm to find its optimal solution. In this problem, the set of destinations is divided into two disjoint sets consisting of 'primary' and 'secondary' destinations, respectively. Due to limited availability of vehicles, the company prefers to transport the goods to the primary destinations first (in Stage-I) and once the demand of the primary destinations is met, the secondary destinations are catered later (in Stage-II) from the left-over availability at various sources. Like a standard bulk transportation problem, the demand of a destination must be fulfilled by one source only, however, one source can cater more than one destinations. The transportation time corresponding to each source-destination link is considered to be known. The objective of the problem is to find such a transportation schedule that provides the minimum sum of transportation times of both the stages. The proposed algorithm, at each iteration, solves a related cost minimizing transportation problem and one of its restricted variants, using a branch and bound technique and converges systematically, to the optimal objective value of the problem. The efficiency of the proposed algorithm is validated through various numerical illustrations. Further, the performance of the algorithm, in terms of CPU time, for various randomly generated instances, is also provided.

2 - Exploring the intersection of Capacitated Vehicle Routing Problem and Centroid-Based Clustering

Abdelhakim Abdellaoui, Loubna Benabbou, Issmail El Hallaoui

Efficiently solving a vehicle routing problem (VRP) is critical for delivery management companies. This work explores the theoretical and experimental connection between the Capacitated Vehicle Routing Problem (CVRP) and Constrained Centroid-Based Clustering (CCBC). Transitioning from CVRP to CCBC represents a shift from exponential to polynomial complexity, utilizing commonly known clustering algorithms, such as K-means.

Our analysis highlights the intrinsic relationship between these problems through illustrative examples and deduced mathematical properties, emphasizing how achieving optimal or near-optimal CVRP solutions strongly depends on starting from specific CCBC centroid regions.

We then propose a CCBC-based approach enhanced to address CVRP, operating in three stages: a constrained centroid-based clustering algorithm generates customer clusters, integrating multi-start centroids, a refined customer assignment metric, and dynamic cluster count adjustment. Subsequently, a Traveling Salesman Problem (TSP) solver optimizes customer sequencing within clusters.

Moreover, our study explores the role of reinforcement learning in identifying centroid regions leading to optimal or near-optimal CVRP solutions. Demonstrating improvements in solution quality and computational efficiency, our findings suggest a transformative approach for delivery management challenges, offering a significant milestone in solving CVRP.

3 - Optimizing Aircraft Line Maintenance Scheduling: A Reinforcement Learning Approach

Syed Shaukat

In the dynamic and complex realm of the airline industry, efficient and reliable scheduling and execution of aircraft maintenance are crucial. Significant challenges in the optimal scheduling of aircraft line maintenance arise from the need to balance maintenance requirements with the limited availability of resources and dynamic operational constraints. Traditional approaches typically employ optimization-based methods to address these issues. However, these methods often struggle to scale up in real-world applications, along with the uncertainties and non-linearities prevalent in such scenarios. Recent advancements in airline scheduling signal a paradigm shift, with simulation-based, data-driven, and AI-enhanced approaches superseding conventional optimization models. This paper introduces an innovative approach that capitalizes on machine learning by integrating a hybrid simulation model with a reinforcement learning (RL) algorithm and dynamic programming search.

Utilizing a hyper-heuristic learning approach, the RL agent explores and learns the optimal scheduling of maintenance tasks, encompassing a criterion-based action space and considering various factors such as aircraft availability, resource allocation, and maintenance requirements. The results surpass the performance of existing optimization-based methods and offer valuable insights that may be applicable to other industries facing similar scheduling challenges in the transportation and supply chain sectors.

4 - GRASP reinforced by Evolutionary Path-relinking for two-echelon covering tour vehicle routing problem

Dang Viet Anh Nguyen, Rajesh Piplani, Aldy Gunawan

We introduce the two-echelon covering tour vehicle routing problem (2E-CTVRP) - a variant of the two-echelon vehicle routing problem to address the transportation and provision of essentials in humanitarian logistics. In the first echelon, a fleet of trucks is responsible for transporting supplies and drones from the depot to satellites located near the affected area. The drones then take on last-mile delivery from the satellites to the demand cluster centroids in the affected area. A clustering algorithm is employed to group the victim location and determine the delivery points within the clusters. This study formulates the 2E-CTVRP as a Mixed Integer Linear Program (MILP) with the objective of minimizing the sum of arrival time of all trucks. A hybrid meta-heuristic, called the Greedy Randomized Adaptive Search Procedure with evolutionary path relinking (GRASP-EvPR), is proposed to solve larger instances within reasonable computational time. The numerical results show that GRASP-EvPR can effectively handle the proposed

instances in terms of solution quality and computational time. Furthermore, this study compares the effects of different truck fleet types on three dimensions of humanitarian logistics: efficiency, efficacy, and equity.

1 - Contextual Stochastic Optimization using Mirror Progressive Hedging

Luca Ferrarini, Louis Bouvier, Axel Parmentier, Vincent Leclere

Prediction and optimization algorithms can be merged to address decision problems involving uncertain parameters linked to known contextual information. Within the framework of Contextual Stochastic Optimization, in this talk we explore the integration of learning models, such as neural networks, with optimization components. Our objective is to learn from a range of policies the most effective one, each parameterized by a neural network. In the specific, our setting is based on hybrid pipelines composed of a machine learning layer where we consider policies encoded by a neural network and concluded by a combinatorial optimization layer. Then, we aim to minimize the expected empirical risk loss on the data training set. To tackle this challenge, we introduce two novel algorithms: the Bregmann Progressive Hedging algorithm, based on a variant of the Progressive Hedging, and the Primal-Dual Mirror Descent algorithm. We present preliminary computational results on the minimum two-stage stochastic spanning tree problem and compare the performance of our learned policy with a well-tailored strategy designed for the problem, but heavily computationally. Our results show that our policy achieves good performance levels while being significantly less computationally demanding.

2 - A data-based approach for solving the Rank Pricing Problem

M. Asuncion Jimenez-Cordero, Salvador Pineda Morente, Juan Miguel Morales

The Rank Pricing Problem is a challenging mixed-integer optimization problem. It aims to determine the optimal pricing strategies of a set of products ranked by customer preferences. Given its NP-hard nature, existing literature offers various exact methodologies. However, these approaches can be intricate to formulate and computationally intensive. In contrast, in this talk, we propose a novel data-based methodology that is simple but effective. Even though our heuristic proposal cannot guarantee to obtain the optimal solution, the numerical results in different instances show its capacity to deliver high-quality results, providing a pragmatic alternative within a short computational time-frame.

3 - Hierarchical clustering with Mixed Integer Linear Optimization Models

Lorena Nácher, Mercedes Landete, Marina Leal Palazón, Vanesa Guerrero, Martine Labbé

Dendrograms are graphical representations of hierarchical clustering that illustrate how individual elements can be grouped into clusters. Depending on the chosen distance measure, different dendrograms can be obtained. The purity measure is used to evaluate the quality of the dendrograms. Purity is defined in terms of the homogeneity in the distribution of observations in the dendrogram with respect to their classes. The first part of this work focuses on single-linkage dendrograms and on purity measure. We introduce the first mathematical optimization model to calculate the purity of single-linkage dendrograms in hierarchical clustering with labeled data. This mixed integer linear

model is based on the ordered median problem. The second part addresses complete-linkage dendrograms. We propose a system of linear inequalities whose solutions are complete-linkage dendrograms. We analyze the impact of ties in the cost matrix in the system and prove that when there are no ties the solution of the system is unique and is the complete-linkage dendrogram while when there are ties the system has as many solutions as alternatives complete-linkage dendrograms the matrix has. This study contributes to understanding the construction and evaluation of dendrograms in hierarchical clustering.

4 - On the optimization of risk scores for continuous predictors

Cristina Molero-Río, Claudia D'Ambrosio

In this talk, we propose a novel Mixed-Integer Non-Linear Optimization formulation to construct a risk score. A trade-off between prediction accuracy and sparsity is sought. Previous approaches are typically designed to handle binary datasets, where numerical predictor variables are discretized in a preprocessing step by using arbitrary thresholds, such as quantiles. In contrast, we allow the model decide for each continuous predictor variable the particular threshold that is critical for prediction. The resulting optimization problem is tested in synthetic and real-world datasets.

1 - Bayesian optimisation for facility location problems

Niyati Seth, Michael Fop

We study the facility location problem under uncertainty where the decisions on where to locate facilities often require estimating different uncertain parameters associated with the problem, for example costs, supply, demand, distances, etc. which may fluctuate with time and circumstances. The recent body of literature has been towards incorporating this uncertainty at various levels. Following and extending this branch of literature, our research aims at developing facility location procedures which account for uncertainty in the model and in the data. To do so, we extend Bayesian optimisation methods for combinatorial structures (BOCS) to solve the facility location problems. Our research presents a novel approach by extending the BOCS method to account for constraints, uncertainty, grid structure and interaction of the allocation nodes. Incorporating constraints in combinatorial domain within the framework of BOCS is challenging. Hence, we propose an extension to the framework by introducing probabilistic reparametrisation for the decision variable, which allows optimisation of the acquisition function on a continuous space. By employing Bayesian optimisation we incorporate uncertainty in the optimisation procedure itself, while allowing for an integrated framework in which the estimation of optimisation variables is data driven. We demonstrate the performance of our method in a simulated study.

2 - A hybrid genetic algorithm for non-regular flexible job shop arising from deconstruction applications

Corentin Juvigny

The field of building deconstruction is a significant contributor to waste generation. However, despite the availability of many waste recovery techniques to valorize this waste, much of it is currently lost due to

poor waste stream management. This study aims to propose a modeling of the deconstruction sector that optimizes dismantling operations and their associated waste flows to raise the recovery rate of the waste, thereby lowering both the financial and environmental costs of the field. This model of the deconstruction sector is based on a bi-level problem. Its upper-level part encompasses the scheduling of operations. The latter hinges on a weighted flexible job shop problem (wFJSP) with release dates and is assessed by a non-regular criterion. We propose a new hybrid disjunctive graph genetic algorithm (HDGGA) for wFJSP, integrating into a genetic algorithm, based on a new encoding, a local search approach employing a novel extension of the disjunctive graph representation that takes account of the idle machine times. The lower-level problem models the allocation of the waste induced. Experiments are carried out on two sets of instances, including one derived from data collected amongst the actors of the field working in the Lille metropolis. The first results exhibit the interest in the genetic-based hybrid method proposed, indicating that it outperforms the existing genetic algorithm-based approach, especially in medium-sized and large-sized instances.

3 - Electrical energy demand forecasting for Türkiye

M. Mücahit Denk, Ceyda Oguz

This study aims to compare the performances of different forecasting techniques to predict electrical energy consumption of Türkiye. The literature on energy demand forecasting generally focuses on multiple regression analysis and time series methods such as ARMA, ARIMA, SARIMAX methods. More recently, machine learning methods have become popular and artificial neural networks are particularly successful in predictions made using time series data. In this study, the energy demand for Türkiye will be predicted by using the data set produced by the local authorities such as Load Dispatch Information System and Load Dispatch Directorates. In addition, economic and environmental factors affecting electricity use will be determined and included in the analysis. For example, economic indicators such as the number of companies, population, low income per capita, and indicators created from air temperature, business days, holidays, festivals, special days of the Hijri and Gregorian calendars will be included in the analysis. As the forecasting method, multiple regression, time series methods, SARIMAX and machine learning methods will be used. Then the performance of these methods will be evaluated, and the best one will be selected.

1 - Pareto optimality in graphs: circulations and colorings

Yiannis Mourtos, Pavlos Eirinakis, Michalis Samaris

Motivated by the growing literature on Pareto-optimal matchings, we examine two fundamental graph problems considering that vertices of a graph have preferences. The first is the circulation problem, in which every vertex sends an amount of flow equal to the one it receives; here each vertex has strict and transitive preferences over its out-going arcs, i.e., over the vertices it sends its flow. The second is the list coloring problem where each vertex has preferences over its available colors. Both problems admit an elegant characterization of the Pareto-optimal solutions, i.e., solutions in which no vertex can receive a better stake (i.e., flow or color) without some other vertex receiving a worse one. Well-known mechanisms, namely Top Trading Cycles or Serial Dictatorship, can find a Pareto-optimal circulation or coloring, respectively. Interestingly, although recognizing Pareto-optimality is easy for circulations, it becomes coNP-complete for colorings. We discuss further

hard optimization problems for both settings, along with special cases that defy hardness by restricting the structure of either the graph or the preferences of its vertices. We also present several motivating applications, review relevant literature, and propose open issues for future work.

2 - (k,l)-anonymity of networks via their k-metric antidimension

Manuel Munoz-Marquez, Elena Fernandez, Dorota Kuziak, Ismael González-Yero

This work focuses on the (k,l)-anonymity of some networks as a measure of their privacy against active attacks. Two different types of networks are considered. The first one consists of graphs with a predetermined structure, namely cylinders, toruses, and 2-dimensional Hamming graphs, whereas the second one is formed by randomly generated graphs. In order to evaluate the (k,l)-anonymity of the considered graphs, we have computed their k-metric antidimension. To this end, we have taken a combinatorial approach for the graphs with a predetermined structure, whereas for randomly generated graphs we have developed an integer programming formulation and computationally tested its implementation. The results of the combinatorial approach, as well as those from the implementations indicate that, according to the (k,l)-anonymity measure, only the 2-dimensional Hamming graphs and some general random dense graphs are achieving some higher privacy properties.

The main contributions of this research are the following: 1. Some theoretical results concerning cylinders, toruses and Hamming graphs are given. 2. We have developed an integer programming formulation for finding the k-metric antidimension of a given graph G. The formulation can be used as a tool to deal with randomly generated graphs as well as with classes of graphs for which their k-metric antidimension is not known theoretically.

Extensions of these results to multiset distances are currently under development.

3 - Adding Relations between a Delegate and Every Other Member of the Same Level in a Complete K-ary Linking Pin Organization Structure

Kiyoshi Sawada

A linking pin organization is a structure in which relations between members of the same section are added to a pyramid organization where there exist only relations between each superior and his direct subordinates. This study proposes a model of adding relations between a delegate and every other member of the same level in a complete K-ary linking pin organization structure where every pair of nodes which have the same parent in a complete K-ary tree is adjacent. When edges between one node and every other node of depth N in a complete K-ary linking pin organization structure of height H are added, the total shortening distance which is the sum of shortening lengths of shortest paths between every pair of all nodes by adding edges is formulated. An optimal depth N such that the communication of information between every member in the organization becomes the most efficient is obtained by maximizing the total shortening distance.

4 - Utilizing Graph Neural Networks for autonomous picking sequence optimization

Dimitrios Tsakoumis, Konstantinos Giannakos, Stathis Pitsos, Pavlos Eirnakis, Giulio Vivo

Warehouse picking is an essential part of assembly production systems. Robotic systems are often utilized to automate this process to increase efficiency and throughput. In this regard, optimizing the picking sequence of the semi-finished products and other components is significant for overall productivity improvement. In our approach, we model the picking process as a Travelling Salesman Problem (TSP), where a robotic agent needs to select the most efficient path to pick multiple different objects from various locations. We investigate different variants of TSP that arise in this setting based on the specificities of the robotic system utilized (e.g., incorporating a dual gripper for picking). Further, we explore the potential of Graph Neural Networks (GNNs) to handle the inherent complexities of such warehouse picking tasks. Although

traditional methods for solving TSP have been extensively examined, GNNs have been recently proposed for solving various combinatorial optimization problems. Our choice for leveraging GNNs in this context arises from their excellence in capturing spatial relationships in graph structured data.

AI for Energy Finance

Stream: Analytics

Invited session

Chair: *Stefan Lessmann*

Chair: *Daniel Traian Pele*

1 - Multivariate Probabilistic Forecasting of Electricity Prices With Trading Applications

Alla Petukhina

A recently introduced approach is extended to probabilistic electricity price forecasting (EPF) utilizing distributional artificial neural networks, based on a regularized distributional multilayer perceptron (DMLP). We develop this technique for a multivariate case EPF with incorporated dependence. The performance of a fully connected architecture and a LSTM architecture of neural networks are tested. The empirical data application analyzes two day-ahead electricity auctions for the United Kingdom market. This creates the opportunity to buy in the first auction for lower price and sell in the second for higher price (or vice versa). Utilizing forecasting results, we develop trading strategies with various investors' objectives. We find that, while DMLP shows similar performance compared to the benchmarks, the algorithm is considerably less computationally costly.

2 - Energy Price Modelling: A Comparative Evaluation of Four Generations of Forecasting Methods

Stefan Lessmann, Alexandru-Victor Andrei, Georg Velez, Daniel Traian Pele

Energy is a critical input in modern economic systems. Much literature has looked into energy forecasting to support critical decisions at various levels and entities; from operational purchasing decisions at individual business organizations to policy-making. In pursuit of maximum accuracy, the field has considered numerous forecasting methods. In this paper, we examine the evolution of methodology across different generations of forecasting methods, starting from classical econometric approaches, over machine learning methods, and earlier sequence learners like LSTMs, to deep transformer networks, which may be regarded as the latest trend in forecasting. We also consider the latest ideas on adopting pretraining and transfer learning, concepts that have revolutionized the analysis of unstructured data and enable modern AI, for time series forecasting. We offer a systematic review of the related literature and categorize different forecasting methodologies. More importantly, using data from EU energy markets, we conduct a large-scale benchmarking experiment, which contrasts the forecasting accuracy of different approaches, focusing especially on alternative propositions for time series transformers.

3 - The impact of energy prices on European stock markets

Robert-Adrian Grecu, Daniel Traian Pele, Alexandru-Adrian Cramer

The aim of this paper is to illustrate the connection between the energy sector and the stock market, specifically how changes in energy prices, such as oil or gas, influence the returns of the main European stock indices. The analysis was carried out at the level of European Union countries, both by taking into account the specific situation of each state, as well as the case of EU countries groups based on different criteria such as geographical region, industrial production level, or economic development status. Even though the EU countries have several common economic characteristics, the results of the analysis show that the impact of energy prices on the stock market can differ significantly from one state to another. Another important aspect observed

in the results is that energy price dynamics have a different type of impact for countries with the highest level of industrial production in comparison with the rest of the EU countries. From a quantitative perspective, the paper studies, on the one hand, the co-movement between variables, and, on the other, the impact of several types of shocks in a VAR framework. Moreover, we focused the analysis on the dynamic links between energy and stock markets; in this sense, models such as Dynamic Conditional Correlation (GARCH) and Time-Varying Parameter (VAR) were applied.

4 - Energy Time Series Forecasting with Neural Architecture Search

Georg Velev, Stefan Lessmann

The importance of accurate planning and operation of energy resources in today's power system has made energy forecasting a popular topic of research. Transformer-based networks have shown promising results on various tasks including energy time series prediction. In this regard, neural architecture search (NAS), which facilitates the automated design of complex neural-based architectures tailored to a specific task, has been reported in the literature to outperform hand-crafted architectures. Therefore, in this research we apply NAS using Reinforcement Learning for the prediction of energy time series. We focus on the search for novel hybrid self-attention modules, which incorporate different functionalities presented in the encoder of Transformer-based frameworks for time series forecasting. Furthermore, we explore the automated design of self-attention components with memory states, in order to examine if the recurrence on a sequence-level could improve the expressive power of Transformer-based models. We report the results obtained from NAS on both real-world datasets and synthetic time series. We benchmark the performance of NAS-related models with Long Short-Term Memory neural cells, and with the Transformer-based frameworks of Informer, Autoformer and Pyraformer.

Distributed and Federated Optimization

Stream: Advances in large scale nonlinear optimization
Invited session

Chair: *Eduard Gorbunov*

1 - TAMUNA: Doubly-Accelerated Distributed Optimization with Local Training, Compression, and Partial Participation

Laurent Condat, Peter Richtarik

In distributed optimization and machine learning, a large number of machines perform computations in parallel and communicate back and forth with a distant server. Communication is typically slow and costly, and forms the main bottleneck in this setting. This is particularly true in federated learning, where a large number of users collaborate to optimize a global model, based on their personal data that are kept private. In addition to communication-efficiency, a robust algorithm should allow for partial participation. To reduce the communication load, two strategies are popular: 1) communicate less frequently; 2) compress the communicated vectors. We introduce TAMUNA, the first algorithm that harnesses these two strategies jointly and allows for partial participation. TAMUNA converges linearly to an exact solution in the strongly convex setting and provably benefits from the two mechanisms of local training and compression: its communication complexity is doubly accelerated, with a better dependency on the condition number of the functions and on the model dimension.

2 - Machine Learning in Untrusted Distributed Environment

Nirupam Gupta

Machine learning algorithms, where the computing system learns from data in order to adjust its behavior, are the key enabler of modern AI-based technologies. This dependency on data, however, is also the Achilles' heel of AI systems. The data, which can come from a wide variety of sources, is not always trustworthy. Some sources can provide erroneous or corrupted data. With current machine learning algorithms, a single "bad" source can lead the entire learning scheme to make critical mistakes. Moreover, to handle the huge amounts of data, machine learning algorithms are often deployed over a large network of machines. Consequently, as the network size increases, the likelihood of machine errors also increases. Indeed, software and hardware bugs are prevalent, and machines can sometimes be hacked by malicious players. Some of these players attempt to corrupt the entire learning procedure, merely for the pleasure of claiming to have destroyed an important system. Others attempt to influence the learning procedure for their own benefit.

Building distributed machine learning schemes that are robust to these events is paramount to transitioning AI from being a mere spectacle capable of momentary feats to a dependable tool with guaranteed safety. In this talk, I will cover some effective techniques for achieving such robustness. Specifically, I will present distributed machine learning algorithms that do not trust any individual data source or computing unit.

3 - Byzantine Robustness and Partial Participation Can Be Achieved Simultaneously: Just Clip Gradient Differences

Eduard Gorbunov

Distributed learning has emerged as a leading paradigm for training large machine learning models. However, in real-world scenarios, participants may be unreliable or malicious, posing a significant challenge to the integrity and accuracy of the trained models. Byzantine fault tolerance mechanisms have been proposed to address these issues, but they often assume full participation from all clients, which is not always practical due to the unavailability of some clients or communication constraints. In our work, we propose the first distributed method with client sampling and provable tolerance to Byzantine workers. The key idea behind the developed method is the use of gradient clipping to control stochastic gradient differences in recursive variance reduction. This allows us to bound the potential harm caused by Byzantine workers, even during iterations when all sampled clients are Byzantine. Furthermore, we incorporate communication compression into the method to enhance communication efficiency. Under quite general assumptions, we prove convergence rates for the proposed method that match the existing state-of-the-art (SOTA) theoretical results.

4 - Beyond spectral gap: the role of the topology in decentralized learning

Hadrien Hendrikx

In data-parallel optimization of machine learning models, workers collaborate to improve their estimates of the model: more accurate gradients allow them to use larger learning rates and optimize faster. In the decentralized setting, in which workers communicate over a sparse graph, current theory fails to capture important aspects of real-world behavior. First, the 'spectral gap' of the communication graph is not predictive of its empirical performance in (deep) learning. Second, current theory does not explain that collaboration enables larger learning rates than training alone. In fact, it prescribes smaller learning rates, which further decrease as graphs become larger, failing to explain convergence dynamics in infinite graphs. This paper aims to paint an accurate picture of sparsely-connected distributed optimization. We quantify how the graph topology influences convergence in a quadratic toy problem and provide theoretical results for general smooth and (strongly) convex objectives. Our theory matches empirical observations in deep learning, and accurately describes the relative merits of different graph topologies.

New problems in logistics under uncertainty

Stream: Stochastic, Robust and Distributionally Robust Optimization

Invited session

Chair: Vibeke Hvidegaard Petersen

1 - Data-driven Drone Pre-positioning for Traffic Accident Rapid Assessment

Zhu Meng, Ning Zhu

A rise in traffic accidents has led to both traffic congestion and subsequent secondary accidents. Effectively addressing this issue requires rapid accident investigation and management. In this paper, we aim to improve the efficiency of traffic accident assessment and investigation with the aid of drone technologies. Our approach involves strategically pre-positioning drones, enabling traffic supervisory agencies to dispatch drones immediately upon receiving an accident report. Methodology-wise, we present a data-driven robust stochastic optimization (RSO) model, which encapsulates the uncertainty of traffic accidents within a scenario-wise Wasserstein ambiguity set. To the best of our knowledge, this is the first study that incorporates covariates, i.e., weather conditions, into the Wasserstein ambiguity set with the CVaR metric. We demonstrate that the proposed RSO model can be reformulated into a mixed-integer programming (MIP) model, allowing an efficient solution approach. Via a real-world dataset of London traffic accidents, we validate the practical applicability of the RSO model. Across various parameter settings, our RSO model exhibits superior out-of-sample performance compared with various benchmark models. The numerical results yield valuable insights for traffic supervisory agencies.

2 - Navigating parametric cost function approximation: A practitioner's guide for sequential decision-making with integer constraints in a production setting

Max Barkhausen

Warren Powell recently coined the term "parametric cost function approximation" (CFA) to describe a practical approach for addressing multistage stochastic decision problems in a deterministic manner. Despite its widespread industrial use, Powell notes a lack of scientific rigor in assessing its effectiveness. In this study, we apply CFA to a real-world multistage lot sizing and inventory management challenge encountered in the automotive sector, where stochastic programming techniques such as SDDiP come with weak convergence guarantees and unacceptable run times. We aim to highlight two key decision points in crafting a CFA algorithm and propose scientific methodologies to tackle them. Firstly, we discuss methods for selecting appropriate parameterization techniques. Second, we explore strategies for identifying optimal parameter values, utilizing Monte Carlo simulation and derivative-free optimization methods. Moreover, we emphasize and explain the importance of evaluating not just the expected value but also the risk associated with resulting policies. Finally, we outline practical strategies for deploying CFA algorithms effectively in production settings marked by varying problem instances and a rolling planning window. Through our investigation, we contribute to enhancing the methodological soundness and practical utility of CFA in real-world decision-making contexts.

3 - Investigating condition-based and predictive strategies for heavy maintenance at offshore wind farms

Vibeke Hvidegaard Petersen, Christian Rognes, Herman Grytbakk Tronsaune, Magnus Stålhane

Until recently maintenance at offshore wind farms have been conducted using a preventive- or condition-based maintenance strategy. However, as more information becomes available, and better prediction models are developed, the goal is to further reduce the cost of

energy from offshore wind farms by moving to a predictive maintenance strategy. In such a strategy, probabilistic models of the future conditions of each component of a wind turbine are used as a basis for planning the maintenance. Heavy maintenance where large components such as blades, generators, etc., are replaced, is one of the costliest types of maintenance as it, besides new components, requires chartering of a specialized jack-up vessel. In this work we investigate how a predictive maintenance strategy affect the cost of heavy maintenance compared to other maintenance strategies. To do this, different strategies are evaluated through a framework simulating the 25-year long lifetime of a wind farm. Each year in the simulation framework, an optimization problem determining how many components to order and the chartering length of a jack-up vessel is solved. As these decisions must be taken well in advance of the maintenance period where component failures and weather conditions governing when the vessel can operate are unknown, this problem is formulated as a two-stage stochastic program. The vessel and component deployment is then simulated as the component failures and weather conditions are realized.

Optimization under Uncertainty in Manufacturing and Supply Chain Management

Stream: Stochastic, Robust and Distributionally Robust Optimization

Invited session

Chair: Berend Markhorst

1 - The Value of Flexibility in Robust Supply Chain Network Design

Amin Ahmadi Digehsara, Amir Ardestani-Jaafari

The study addresses the supply chain network design problem (SC-NDP), focusing on strategic, long-term decisions that integrate flexibility and demand information to enhance cost efficiency. We examine five policies that incorporate new flexibilities at strategic and operational levels to optimize the SCNDP. Initially, we explore a model where local production meets demand. We expand this to include scenarios where production capacity can satisfy demands across different locations and shared among facilities with preestablished links. Unlike traditional models that fix production capacity early, we also consider policies allowing production decisions to be deferred until demand is known, favoring a make-to-order strategy. Our analysis employs a two-stage robust optimization framework for which we introduce a novel computationally efficient exact (based on Column-and-Constraint Generation (C&CG)) and multiple approximation techniques (based on Linear Decision Rules). Our findings reveal that capacity sharing significantly reduces costs and shortage risks, showcasing its superiority over delayed production decisions, particularly under moderate uncertainty. The study concludes by applying these insights to a real-world case, offering practical design recommendations.

2 - Stochastic optimization with automated number of storage tank selection for crude oil scheduling

Hasan Sildir, Damla Yalcin, Ozgun Deliismail, Basak Tuncer

In the field of process system engineering (PSE), particularly in the oil and gas industry, a novel approach is presented that significantly enhances sustainability. This approach is characterized by integrating effective scheduling and planning strategies that transition from traditional deterministic optimization to a robust framework. This framework is adept at managing the uncertainties inherent in the industry, a challenge often overlooked in conventional methods. Central to this new strategy is the development of a Mixed-Integer Nonlinear Programming (MINLP) model for crude oil tank farm management. This

model integrates deterministic mathematical principles with stochastic components to address the unpredictability of oil volumes and market prices, aiming to improve operational efficiency and promote oil sector sustainability. Furthermore, the integration of the Industrial Internet of Things (IIoT) and Process Intensification (PI) optimizes value chains, marking a substantial advancement in addressing the complex challenges of current industrial processes and establishing a foundation for future sustainable industrial developments. This comprehensive approach balances ecological, social, and economic dimensions and represents a significant step towards the sustainable development in chemical engineering and PSE, combining advanced technologies with robust optimization techniques.

3 - Sailing through uncertainty: mathematical optimization for ship pipe routing in the energy transition

Berend Markhorst, Joost Berkhout, Alessandro Zocca, Jeroen Prun, Rob van der Mei

The maritime industry must prepare for the energy transition from fossil fuels to sustainable alternatives, which makes the design of future-proof ships even more important. In the design phase of a ship, it is currently uncertain which fuels it will use in the future due to many external factors. In fact, a ship typically sails for decades, increasing the likelihood that it will have to use different fuels over its lifetime. When changing fuels, pipe route design, which ensures a connection between the fuel tanks and the engine rooms, is expensive, time-consuming, and mainly done by hand. Motivated by this, together with maritime experts, we propose a mathematical approach for modeling uncertainty in automatic pipe routing with deterministic, stochastic, and robust optimization. All three approaches are based on state-of-the-art integer linear optimization models for the Stochastic Steiner Forest Problem and adjusted to the maritime domain using specific constraints for pipe routing given by the maritime experts. We compare the approaches using both artificial and realistic data of a commercial ship design company and show that considering uncertainty using stochastic optimization and robust optimization leads to cost reductions. Additionally, we extend our approaches with decomposition methods to solve large-scale (industry) instances.

Chair: *Markus Sinnl*

1 - On computing the Edgeworth-Pareto hull of multi-objective mixed-integer linear programming problems via an outer approximation algorithm

Markus Sinnl, Fritz Bökler, Sophie Parragh, Fabien Tricoire

In this talk, we present an outer approximation algorithm for computing the Edgeworth-Pareto hull of multi-objective mixed-integer linear programming problems (MOMILPs). It produces the extreme points (i.e., the vertices) as well as the facets of the Edgeworth-Pareto hull. The algorithm relies on a novel oracle that solves single-objective weighted-sum problems and we show that the required number of oracle calls is polynomial in the number of facets of the convex hull of the extreme supported non-dominated points in the case of MOMILPs. Moreover, for the special case of multi-objective linear programming problems, by generating the Edgeworth-Pareto hull the algorithm solves the problem to global optimality. A computational study on a set of benchmark instances from the literature is provided.

2 - Lagrangean lower bounding and math-heuristics for approximating the set of non-dominated points of a computationally demanding bi-objective MILP

Ann-Brith Strömberg, Gabrijela Obradovic, Felix Held, Kristian Lundberg

We consider a computationally demanding bi-objective MILP, arising from an industrial maintenance and workshop scheduling problem subject to a turn-around time contract. Since, for industrial scale instances, this problem cannot be solved in reasonable computing time, we employ (i) so-called job variables in the workshop model, and (ii) a lower bounding procedure based on Lagrangean relaxation of the complicating constraints of an epsilon-constraint scalarized problem combined with math-heuristics to identify approximately non-dominated feasible points. A Lagrangean dual of the scalarized problem is maximized using subgradient optimization, which is shown to provide lower bounding functions of the objective of the scalarized problem over the domain of the epsilon-constrained objective. As a means to reduce computational complexity we introduce so-called job variables, however resulting in an in-definiteness of the Lagrangean dual variables. This is remedied by aggregating, over jobs, the constraints defining the objective, which in turn entails a relaxation of the scalarized problems in terms of lower optimal values. To mimic the turn-around time contract, the aggregated variables' values are split into values for the original job variables. The lower bounds computed are, however, still valid, albeit slightly weaker as compared to when constraint aggregation is not employed. A topic for further research is tightening of these lower bounds.

3 - An interactive multi-objective algorithm using preference cones

Mariana Mesquita-Cunha, José Rui Figueira, Ana Barbosa-Povoa

Multi-objective problems are common real-world problems. However, computing the whole Pareto front and analyzing it to make a decision is often impractical. Therefore, we propose an interactive algorithm to help the decision-maker (DM) reach the most preferred solution. The interactive algorithm alternates between generation stages, using a representation method based on the epsilon-constraint algorithm, and analysis stages, in which pairwise comparisons are required. Convex preference cones are used to adapt the search region based on the pairwise comparison. To that end, the H-representation of the 3-pointed convex cone is developed so that those types of preference cones can be included as inequality constraints in the generation phase. Moreover, two boosting strategies are put forward to increase the algorithm's convergence. The algorithm is tested on different sets of multi-objective problems, namely binary and integer problems with multiple constraints. The DM's preferences are simulated through linear and Chebyshev value functions with different weight vectors. The algorithm has proven effective, converging to the most preferred point in the Pareto front, and the boosting strategies improved the efficiency of the algorithm. Furthermore, the advantage of increasing the size of the solution subset shown to the DM in each iteration is made clear in those instances in terms of iterations and computational time.

Advances in polynomial optimization and its applications

Stream: Conic Optimization: Theory, Algorithms, and Applications

Invited session

Chair: *Bram Bekker*

1 - Term-sparse polynomial optimization for the design of frame structures

Marouan Handa

This work investigates efficient solution to two fundamental problems in topology optimization of frame structures. The first one involves minimizing structural compliance under linear-elastic equilibrium and weight constraint, while the second one minimizes the weight under compliance constraints. These problems are non-convex and generally challenging to solve globally, with the non-convexity concentrated in a polynomial matrix inequality. Recently, these problems were tackled using the moment-sum-of-squares (mSOS) hierarchy. However, only smaller instances can be solved globally. Here, we aim to improve the scalability of solution to these problems by using the mSOS hierarchy supplemented with the Term Sparsity Pattern technique (TSP). Due to the unique polynomial structure of our problems in which the objective and constraint functions are separable polynomials, we further improve scalability by adopting a reduced monomial basis containing non-mixed terms only. From extensive numerical testing, we conclude that these techniques allow for a global solution to larger instances and accelerate the solution of the problems significantly.

2 - Weight minimization of frame structures under free-vibration eigenvalue constraints with polynomial optimization

Marek Tyburec

Topology optimization of frame structures that minimizes the weight while respecting free-vibration eigenvalue constraints presents a challenging nonconvex polynomial optimization problem. We address this challenge using a nonlinear semidefinite programming formulation, casting it as a bilevel program. This reformulation offers a unique structure: a quasiconvex, univariate lower-level problem that searches for scaling of fixed cross-section area ratios and an upper level that optimizes these ratios. We establish conditions for the lower-level problem solvability and demonstrate how to construct feasible solutions for the original polynomial semidefinite program. Given a feasible point, we prove that the convergence conditions of the Lasserre hierarchy are satisfied. By solving this hierarchy of convex relaxations, we obtain lower bounds. We further show that the relaxed solutions satisfy the conditions for the feasibility of the lower-level problem and thus enable us to construct feasible upper bounds in each relaxation. With this, we introduce a simple sufficient condition for global ϵ -optimality and prove that the optimality gap ϵ approaches zero in the limit when the set of global minimizers is convex. Numerical examples illustrate the convergence of the hierarchy in a finite number of steps.

3 - SDP hierarchies for distance-avoiding sets on compact spaces

Bram Bekker

Witsenhausen's problem asks for the maximum fraction αn of the n -dimensional unit sphere that can be covered by a measurable set containing no pairs of orthogonal points. We extended well known optimization hierarchies based on the Lovász theta number, like the Lasserre hierarchy, to Witsenhausen's problem and similar problems. These hierarchies are shown to converge and are used to compute the best upper bounds known for αn in low dimensions.

4 - A novel branch and bound algorithm for solving the linear multiplicative programming problems

Jinyu Dai

In this talk, we propose a novel branch and bound algorithm for solving the linear multiplicative programming (LMP) problem. A new quadratic relaxation is proposed. We first show that the Hessian matrix of the multiplication of two linear functions has a decomposition form, given by the difference of two rank-one matrices, resulting in a decomposition each quadratic term of the objective function. And then the minus term is relaxed into a linear one. To find the global optimal solutions, branch and bound method is adopted. Theoretical analysis is provided that guarantees the convergence of our algorithm. Numerical experiments show that the new algorithm runs faster than several typical algorithms for certain types of LMP.

1 - Real-Time Temperature Control for Refrigerated Trucks: A Multistage Stochastic Programming Approach

Francesco Giliberto

In this work, we study the problem of transporting temperature-sensitive products in refrigerated trucks, where maintaining temperatures within specified ranges is crucial to prevent quality degradation. Innovative routing models are characterized by several limitations, such as the lack of a direct link between temperature and the variables influencing its dynamics and the assumption of deterministic scenarios. Our work introduces a novel model that treats temperature as a dynamic variable influenced by multiple factors, including cooling unit operation, and incorporates uncertainties such as door opening durations and initial product temperatures. Our approach involves optimizing a high-frequency control policy for cooling units by casting the problem as a multistage stochastic program, with each client stop representing a stage. This method poses computational challenges due to the extensive number of stages and the complexity of thermodynamic modeling. To address this, we employ the Stochastic Dual Dynamic Programming algorithm and validate our methodology through a case study with real-world data from a specialized Dutch logistics company. The findings demonstrate that our strategy surpasses both deterministic lookahead strategy and current industry practice in maintaining optimal product temperatures while minimizing energy consumption. This advancement holds significant potential for enhancing the efficiency and sustainability of refrigerated transport logistics.

2 - Dynamic Capacity Management in 5G Networks

Demet Batur, Jennifer Ryan, Mehmet C Vuran

We study the decision problem faced by the operator of a private 5G network, known as a private cell, who must allocate available capacity to meet the resource needs of the primary user of the network. The operator may lease excess capacity to external secondary users to generate additional revenue. Private cells are privately owned wireless networks. Industries such as manufacturing and transportation utilize private cells to prevent downtime for their automated operations. Private cells use network slicing, a technological advancement made available by 5G, to meet differentiated application needs. Under slicing, the network's resources can be dynamically segmented to support specific applications. Network slicing also allows the resource capacity currently not used by the primary user to be leased to a secondary user, such as a broker. Given this setting, we study the problem faced by an operator whose main responsibility is to serve the slice instances of the private cell's primary user but who can also lease excess resources to a secondary user to generate revenue. Primary user slice instances require a specific combination of network resources, such as spectrum, computation, or storage. The operator determines which instances will be admitted to the network for service and which resources can be leased to the secondary user. We use an MDP model to formulate this problem and characterize the optimal admission and leasing decisions.

3 - Optimal Replacement of Mission-Based Systems with Partially Observable Degradation Levels

Bora Cekyay, Suleyman Ozekici

We consider an optimal replacement problem for a mission-based system with partially observable degradation levels, where a mission process modulates the system's degradation process. The system is partially observed at predetermined time points, where perfect information related to the mission process (fully observable) is obtained, and only partial information related to the system's degradation level (partially observable) is obtained. We formulate the optimal replacement

problem as a partially observable Markov decision process to minimize the long-run expected total discounted cost. We provide sufficient conditions to guarantee a control-limit type optimal replacement policy.

4 - Standardized moments of waiting

Dominik Berbig

We all have to wait. Sometimes longer, sometimes shorter. Thanks to queuing theory, we know why this is the case. However, under the usual assumption of a continuous-time domain, we do not really know how long we have to wait. In the case where the Markov property does not hold for the inter-arrival-time distribution, only estimations for the waiting times exist. They are rather easy to calculate as they are solely based on the mean and variance of the distributions, everything else is neglected. But these estimates can be arbitrarily inaccurate and offer no guarantee of quality. One solution is to apply the discrete-time domain. Here, the entire distribution is known, exact parameters can be calculated. However, this approach is much more complex. Thus, an intermediate solution is required which is less complex but more precise. Therefore, the effect of other standardized moments must be analyzed and taken into consideration. First corresponding analyses especially regarding inter-arrival times have recently been carried out and have provided initial indications. In this paper, these results are reflected on and taken as basis. In addition, experiments specifically with regards to service-time distributions are presented and the results are compared. Corresponding findings and possible next steps are presented in this paper serving as a basis for discussion for future work as this is important to calculate correct buffer sizes.

1 - Exploring the effects of usefulness and ease of use of reports on transactional decisions: a case of ERPsim game

Sung Shim

ERPsim is a set of computer-based simulation games for the SAP enterprise resource planning (ERP) system in which participants use the system to manage their virtual company in a competitive market. While many students and businesspeople have come to use ERPsim games in learning about the SAP ERP system, little is known about how useful and how easy to use reports available in the system are during ERPsim games. This study attempts to evaluate the usefulness and ease of use of reports and their effects on transactional decisions during ERPsim games, using data from a survey of college students who used the Distribution ERPsim game in a course on ERP systems. Previous research shows that the usefulness and ease of use of information are crucial factors that determine the effectiveness of decision-making. The results of this study would be helpful to those who use ERPsim games as well as those who design ERPsim games and further the SAP ERP system in which ERPsim games run. The results are based upon the perceptions of users in a simulated setting; however, they could provide valuable insights into the effects of usefulness and ease of use of reports on transactional decisions.

2 - State-aware online self-supervised domain adaptation for bearing remaining useful life prediction

Kyeonggeun Park, Jun-Geol Baek

Transfer learning methods for remaining useful life (RUL) prediction of rolling bearings have rarely focused on online feature drift scenario. Bearing degradation trends are categorized into several states, as normal, slight degradation and severe degradation states, each with distinct feature distributions. During the degradation process, changes in state lead to online feature drift, which reduces the accuracy of RUL prediction. To overcome this challenge, this study suggests aligning feature distributions for each state using state-awareness to adapt to online domain shifts. State awareness is achieved by deriving the Health Index (HI) based on the Wasserstein distance, applying smoothing techniques, and statistically detecting the First Prediction Time (FPT) and acceleration point. This provides state label during online degradation process. The online self-supervised domain adaptation model leverages the current degradation data as target, with the source domain comprising previous run-to-fail data. Aligning feature distributions between these domains and states enhances RUL prediction accuracy by extracting domain-invariant and domain-specific features, as well as state-invariant and state-specific features. Experimental validation using IEEE PHM Challenge 2012 bearing data demonstrates the effectiveness of the proposed methodology in achieving state awareness and accurate RUL prediction through online self-supervised domain adaptation in dynamic operating environments.

3 - Dimensionality reduction techniques to support insider trading detection

Adele Ravagnani, Fabrizio Lillo, Paola Deriu, Piero Mazzarisi, Francesca Medda, Antonio Russo

Identification of market abuse is an extremely complicated activity that requires the analysis of large and complex datasets. We propose an unsupervised machine learning method for contextual anomaly detection, which allows to support market surveillance aimed at identifying potential insider trading activities. This method lies in the reconstruction-based paradigm and employs principal component analysis and autoencoders as dimensionality reduction techniques. The only input of this method is the trading position of each investor active on the asset for which we have a price sensitive event (PSE). After determining reconstruction errors related to the trading profiles, several conditions are imposed in order to identify investors whose behavior could be suspicious of insider trading related to the PSE. As a case study, we apply our method to investor resolved data of Italian stocks around takeover bids.

Nonsmooth optimization algorithms II

Stream: Nonsmooth Optimization

Invited session

Chair: Puya Latafat

1 - On best proximity points

Monica Stanciu

The aim of this contribution is to present the existence of some best proximity points for different type of operators that respect implicit type inequalities on generalized metric spaces. Those operators are defined using various classes of mappings with adequate properties of monotony, continuity or other specific inequalities. The passing from classic metric spaces to generalized metric spaces is made by an additional condition that ensures the existence of a sequence that will converge to a best proximity point. Those points are also a part of the set of zeros for two lower semi continuous functions. Consequences related to some fixed point results are also provided.

2 - Newton-type proximal gradient method with quadratic subproblem approximation for unconstrained optimization with L1-regularizer

Yasushi Narushima, Hiroshi Ben

We consider an unconstrained optimization problem whose objective function is expressed by the sum of a continuously differentiable function and an L1-regularizer. One approach for solving such problems, the Newton-type proximal gradient method, has gained attention. In Newton-type proximal gradient methods, we need to solve a sub-problem to obtain the scaled proximal mapping at each iteration. However, the computational cost of solving this subproblem is sometimes very high. In our study, we address this difficulty by approximating the sub-problem in a more easily solvable form. Concretely, we approximate the L1-norm within the objective function of the subproblem using a quadratic function. This method allows the solution to the subproblem to be found using only simple calculations. However, the obtained solution requires a system of linear equations to be solved. In response to this issue, we calculate an approximation to the Hessian in the Newton-type proximal gradient method using a memoryless quasi-Newton method. In addition, we use the Sherman-Morrison-Woodbury formula to obtain the closed-form solution to the inverse matrix with reduced computational costs. Thus, we easily obtain an approximate solution for the scaled proximal mapping. Based on the proposed method for the subproblem, we give an algorithm of Newton-type proximal gradient methods. In addition, we show the global convergence of the proposed algorithm under some standard assumptions.

3 - A smoothing barrier augmented Lagrangian gradient-based method for constrained bilevel programs

Mengwei Xu

Gradient-based methods are known for their efficiency in solving unconstrained bilevel programs. However, when dealing with constrained bilevel programs, the application of this method becomes challenging due to the strict complementarity condition required for the continuous differentiability of the lower level solution mapping within the Karush-Kuhn-Tucker system. To tackle the lower level problem with inequality constraints without relying on strict complementarity, we propose a family of smoothing functions to approximate the primal-dual solution mapping based on the smoothing barrier augmented Lagrangian function, which ensures the preservation of the continuously differentiability and the convexity of the lower level problem. By approximating the bilevel program as single-level constrained problems, we adopt a hybrid approach that combines the gradient-based method with the augmented Lagrangian method. This allows us to effectively solve the constrained bilevel programs. We prove that any accumulation point generated by the algorithm is a Clarke stationary point of the bilevel problem. Importantly, unlike conventional smoothing function methods, the accumulation point can also be a Bouligand stationary point under an additional verifiable condition.

(SPD) matrix, so the objective function is well-defined on the feasible set. Without loss of generality, we also assume the numerator is strictly convex with an SPD matrix. Contrary to the case where the numerator is a linear function, a stationary point (SP) of StFQQP is not necessarily a global minimum because the objective function is not quasi-convex.

We introduce a new sequential algorithm for the StFQQP, exploiting a reformulation as a mathematical program with complementarity constraints derived from the KKT conditions of the StFQQP, which are in the form of the so-called symmetric Eigenvalue Complementarity Problem (EiCP). Solving an EiCP is then equivalent to computing an SP to the StFQQP.

Preliminary computational experiments with various test problems suggest that the sequential algorithm is a promising technique for solving the StFQQP.

2 - Existence results for coupled systems of variational inequalities

Nicusor Costea

In this talk the existence of solutions for a system consisting of two inequalities of variational type is discussed. Each inequality is formulated in terms of a nonlinear bifunction and a coupling functional. We consider two sets of assumptions for each of the functional involved in the formulation of the system and show that if the constraint sets are nonempty, closed, convex and bounded then the system possesses at least one solution regardless of the assumption imposed on each functional. If one of the constraint sets is unbounded, then a coercivity condition is needed to ensure the existence of solutions. We provide two such conditions. The theoretical results are then employed to establish the existence of weak solutions for a mathematical model which describes the antiplane shear deformation of a cylinder made of a nonlinear elastic material and a rigid foundation.

3 - Approximate computation of the Shapley value in cooperative games on transportation networks via machine-learning techniques

Mauro Passacantando, Giorgio Gnecco, Yuval Hadas, Marcello Sanguineti

To quantify the relative importance of nodes in a network, one possible approach uses the concept of centrality. However, classical measures of centrality do not consider how the network behaves if any subset of nodes is removed from the network and, when applied to transportation networks, issues such as arc capacity, route choice, and congestion are not taken into account. Alternative measures of centrality based on game theory are more effective, such as those based on the Shapley value. The Shapley value is a well-established concept in cooperative game theory, used as a metric for assessing the significance of each player in a transferable utility game. Recently, it has found application in gauging the importance of individual arcs or nodes within transportation networks. However, the exact computation of the Shapley value is often computationally expensive, particularly in the context of extensive networks. Here, we approximate the Shapley value in a transferable utility game defined on a network, wherein the network's characteristics are parameterized by a variable of interest (e.g., the traffic demand). Smoothness properties of the Shapley value as a function of the parameter are investigated and exploited to motivate using machine-learning techniques for its approximate computation.

Invited session

Chair: Laura Carosi

1 - Decision-making for the International Management Excellence Award using the PSI-COCOSO Hybrid Multicriteria Method

Solange Fortuna Lucas, André Luiz Carneiro de Vasconcellos, Marcos dos Santos, Carlos Francisco Simoes Gomes, Miguel Ângelo Lellis Moreira, Felipe Fortuna Lucas

Several countries have adopted awards as a stimulus and recognition for companies that stand out in the management of the quality of products and services. Stakeholder involvement must be infiltrated into the values and mission of companies to reinforce, mainly, corporate governance, providing transparency and accountability to the developed businesses. The evaluation of an organization's performance should be related to the multiple interests pursued by the corporation, including the expectations achieved by its stakeholders. This work shows how to evaluate the companies that apply for an international quality award, based on the management excellence model presented, using the Preference Selection Index Method (PSI) to find the weighting of the criteria and the Combined Compromise Solution (COCOSO) Method for the ordering of the alternatives. The criteria used to evaluate companies are Research and Development (R&D), People, Projects, Leadership, Processes, Information and Knowledge, Operations, and Sustainability in Business according to the stage scale created to represent the evolution of each company's criteria from the perspective of the internal environment. Company D is the winner of the Management Excellence Award. The result is quite coherent, as it is the only company that already presents 2 (two) criteria in the higher stage, that is, the R&D and Leadership criteria have already reached the stage of Criterion Implemented with Excellence (grade 5).

2 - Leveraging Generative AI for Enhanced Digital Service Platforms: A Comprehensive Analysis of Critical Success Factors

Ruchi Mishra, Rajesh Singh, Onkar Mishra

Generative Artificial Intelligence (AI) presents a compelling opportunity for advancing digital service platforms by enabling the creation of dynamic, personalized content and experiences. This paper aims to explore and analyze the critical success factors (CSFs) essential for the effective integration of generative AI within digital service platforms. Through an extensive review of existing literature and expert insights, key factors influencing the successful implementation of generative AI in digital service contexts were identified. Subsequently, employing qualitative analysis methodologies, a robust framework of CSFs was developed, encompassing aspects such as algorithmic sophistication, data quality, user engagement, platform scalability, and ethical considerations. Moreover, the study investigates the intricate interplay between these factors to elucidate their collective impact on the performance and sustainability of digital service platforms leveraging generative AI capabilities. The findings underscore the significance of addressing diverse challenges inherent in the adoption of generative AI, including algorithmic biases, privacy concerns, and user acceptance. This research contributes valuable insights into the critical factors shaping the effective deployment of generative AI in digital service platforms, offering actionable guidance for platform developers, service providers, and policymakers seeking to harness the potential of this transformative technology.

3 - EU Waste Recycling Targets: Where are we at? A Performance Evolution Assessment

Laura Carosi, Giovanna D'Inverno, Trinidad Gomez, Maria Molinos-Senante, Giulia Romano

Over the last decade the European legislator has set ambitious recycling targets for municipal waste and packaging waste so to achieve a more circular economy and to contribute to the European Green Deal's sustainability goals. In this paper, we evaluate the European countries performance evolution with respect to the constantly evolving waste management legal framework and their response to the definition of increasingly demanding targets. To do so, we suggest an innovative dynamic composite indicator to evaluate the country performance with respect to different packaging waste categories and taking into account their deviation from the set targets. In particular, the proposed synthetic indicator distinguishes targets in terms of essential thresholds

and aspiration levels. The essential thresholds do not allow for compensations between strengths and weaknesses of the evaluated units and grants that certain fundamental standards are met. The aspiration levels are targets that countries should aim at to foster their sustainability, but they are not compulsory. We monitor the evolution of 27 European countries from 2015 to 2020, where the packaging legislative framework has undergone important developments. The tool provides policy-relevant findings, important to identify best practices and to define priority actions so to enhance the transition of lagging-behind countries towards a more circular economy.

Planning Techniques for Decision Support

Stream: Decision Support Systems

Invited session

Chair: *Laura Wolf*

1 - Proposal for an ML-supported ETCS L2 Data Point Plan Review Process

Salome Vogel, Arturo Crespo Materna, Cedric Steinbach

The timely rollout of ETCS L2 as a standardized train control system in Europe is depending on capacities of human planning experts, which are especially limited in the field of plan review. Central requirements for ETCS L2 data point (DP) plan review are, to assess the completeness and correctness of the ETCS L2 DP plan, following a different logic than the plan creation. This proposal presents an approach to review the completeness of the ETCS L2 DP plan. The rule-based nature of the underlying planning rules and regulations leads to the choice of a supervised learning (SL) algorithm. To assess completeness, in this approach the ETCS L2 DP plan under review is segmented into functional and spatial areas, with specific DP types assigned to particular reference points within those areas. The SL algorithm learns in which cases, which type(s) of DP are required within each area. Training data are existing ETCS L2 DP plans for different scenarios by human experts. An important benefit of the SL algorithm is that it learns from pattern in the training data instead of applying the planning rules and regulations 1:1, hence allows a plan review following a different logic than plan creation. Additionally, the plan review supported by the proposed SL algorithm provides decision support for plan reviews carried out by human experts. Thereby it facilitates a faster rollout of ETCS L2, contributing to interoperability, resilience and thus increasing rail capacity in Europe.

2 - Decision Support Models for Strategic Decision Making in Industry 4.0

Katarzyna Gdowska

Solving strategic-level decision problems necessitates integrating advanced data analytics and decision support models, which is particularly crucial in the data-driven Industry 4.0. This paper offers an overview of strategic decision challenges across industries, exploring various approaches, optimization problems, and solving techniques. Rather than following the conventional path of reviewing solely peer-reviewed academic publications, this study also systematically surveys industry literature. The nuanced needs and preferences driving strategic decision-making processes are revealed with a deliberate emphasis on decision-makers perspectives over intricate tool presentations. Through this dual review of academic and industry literature, the paper delineates the utilization landscape of decision support methods and tools, elucidating the rationale behind the choices made. This approach illuminates prevailing practices and reveals latent requirements, empowering decision-makers with the insights needed for informed method and tool selection.

3 - A comparison of two approaches to hardware capacity planning for cloud infrastructure under demand uncertainty

Laura Wolf, Patrick Jahnke, Stefan Nickel

Cloud computing and especially Infrastructure-as-a-Service (IaaS) are becoming more and more relevant in industrial applications. In IaaS, cloud providers offer customers resources such as compute, network and storage. From the provider's point of view, the question arises of how many physical resources are required to cover the uncertain demand, to achieve utilization targets and deal with fluctuating workload demand. This decision must be made from a midterm perspective due to increasing supply chain cycles. We compare two approaches to deal with this hardware capacity planning problem for cloud infrastructure under demand uncertainty (CPCI_DU) to determine the needed capacity of a datacenter. The decision problem is modeled as a two-stage stochastic optimization problem and solved optimally. The results are evaluated using metrics from stochastic optimization such as the value of stochastic solution and the expected value of perfect information. This method is compared to an optimization-simulation loop. Here, the deterministic optimization problem is solved on the first stage and the impact of uncertainty is evaluated in the subsequent simulation. This optimization-simulation loop is executed until a prespecified stopping criterion is reached. The results show the strengths of the respective approaches to enable robust hardware planning.

Human Centric Analytics (HCA)

Stream: Making an Impact
Invited session

Chair: Christina Phillips

Chair: Ruth Kaufman

1 - Human Centric Analytics (HCA): How To Foster The Human Centred Development Of Analytics That Augment Human Work Effectively."

Making An Impact, Christina Phillips

In situations of high uncertainty and high human involvement, it can be difficult to implement analytical tools; on the other hand those tools can serve to reduce and define the uncertainty. To achieve this level of use the human actors involved need to be empowered to understand and utilise the data that they produce and use. This requires both learning and experiment in a safe and creative space as mathematical tools, data and humans come together.

In this workshop we will use examples from industry interventions to introduce the ideas and concepts around HCA. We will discuss what works and what doesn't, and why that is, and develop skills around choosing the right structuring methods and analytical approaches for differing situations.

Design is a key part of the process, and we will look at ways to keep in mind the iterative and empathetic journey that this helps to facilitate, while also looking at ways to integrate HCA into common working practices such as lean projects.

DEA methodological developments II

Stream: Data Envelopment Analysis and its Application
Invited session

Chair: Paul Rouse

1 - Path-based DEA models

Jakub Hrdina, Maria Trnovska, Margareta Halicka

Data envelopment analysis (DEA) models appear in the envelopment and the multiplier form, which are in a primal-dual relationship. Both forms are essential for the proper interpretation and application of the model. New models are typically presented in the envelopment form, yet if they are not linear, it can be more challenging to acquire their dual counterparts. In this contribution, we focus on path-based DEA models, which search for the benchmarks by specifying various parametric paths running from the assessed unit to the boundary of the technology set. The class of path-based models includes well-known models such as the BCC input and output models, the hyperbolic distance function model and the general directional distance function model. For a general scheme of path-based models in the envelopment form we derive the general multiplier form of path-based models. Since path-based models in general are not linear, we study the duality relations between the primal-dual pair of envelopment and multiplier path-based models. Finally, we focus on the multiplier form of the BCC input and output models, the general directional distance function model and the general hyperbolic measure model using the derived general multiplier form of path-based models.

2 - Multiplier form of path-based DEA models and returns-to-scale measurement

Maria Trnovska

Path-based models represent a large class of DEA models in which the efficiency score and projection point are derived using a path running from the assessed unit to the boundary of the technology set. The class includes the input and output-oriented radial models, the directional distance measure and the hyperbolic distance measure models as special cases. The particular models fit a general envelopment scheme that allows to derive its dual (multiplier) form, and to analyze the primal-dual properties for the whole class of models. Based on this primal-dual relationship, we describe a two-way connection between the supporting hyper-planes of the technology set and the optimal solutions of the multiplier model and utilize it in the returns-to-scale measurement. We analyze and compare different approaches to the returns-to-scale measurement, depending on whether the supporting hyper-planes contain the (not necessarily strongly efficient) projection point or only strongly efficient benchmarks. The results are demonstrated in numerical examples.

3 - Revenue Functions Are Nonconcave in the Inputs When the Technology is Nonconvex: The Unbearable Lightness of Convexification

Kristiaan Kerstens, Oleg Badunenko, Jafar Sadeghi

Revenue functions are studied under the assumption that the technology is nonconvex. More specifically, we show theoretically that the convex revenue functions are larger or equal to the nonconvex revenue functions. However, with one input and constant returns to scale (CRS) technologies, both these revenue functions coincide. Including more inputs or varying returns to scale assumption (e.g., variable returns to scale, VRS) results in differences between the convex and nonconvex revenue functions. We use USA state-level agricultural data to showcase our theoretical result empirically. We first visualize the revenue functions under constant and variable returns to scale assumptions and demonstrate that the former is identical irrespective of whether technology is convex or nonconvex while the latter revenue functions are different. We further show graphically that the convex or nonconvex revenue functions are different both under CRS and VRS with 4 inputs. Additionally, we use statistical tests (equality of densities and stochastic dominance) to show that the convex or nonconvex revenue functions are statistically different. Finally, we perform scale efficiency analysis to show how using the convexity assumption may result in false policy implications.

4 - Some problems with benefit of the doubt models

Paul Rouse, Maryam Hasannasab, Dimitris Margaritis

Benefit of the Doubt (BoD) models are increasingly popular in the literature with flexibility around technology assumptions and ease of understanding for managers and practitioners. Most of the focus has been on the efficiency scores with little attention paid to benchmarking in terms of target values and the appropriateness of peers. Specifically, there are problems that arise when weight restrictions are imposed, particularly the effects on efficient frontiers, further compounded when virtual weight restrictions are used. These affect target values and benchmarking peers with nonintuitive effects as the lower bounds on the restrictions are increased. A further question concerns how size can be incorporated to allow for scale economies. Further issues arise with respect to units-invariance properties for output oriented models. We illustrate these issues using sustainability data comprising GRI measures and provide some thoughts towards addressing these problems.

Mathematical programming for machine scheduling

Stream: Lot Sizing, Lot Scheduling and Production Planning

Invited session

Chair: [Safia Kedad-Sidhoum](#)

1 - MILP formulations with a logarithmic number of binary variables for planning and scheduling

Alain Hait

The way to represent the position of an activity on the time axis is at the heart of planning and scheduling models. A first distinction is done between continuous and discrete time formulations. This work focuses on discrete-time models that consist in choosing the start time of an activity among a discrete set of successive values. For this purpose, several time-indexed formulations have been proposed. They use as many binary variables as time steps on the horizon for each activity. The number of variables could be significantly reduced using binary encoding to represent the set of time values, but the attempts to determine activity start times this way have generally led to models with poor relaxations. Vielma and Nemhauser have proposed formulations to model disjunctions with a logarithmic number of variables and constraints. They study the association with SOS2 variables in order to model piecewise linear functions, but their models are also suitable for time-indexed formulations in scheduling problems.

This work presents the adaptation of Vielma and Nemhauser's formulation to time-indexed scheduling models. The comparison is done with classical time-indexed formulations through the Resource-Constrained Project Scheduling Problem (RCPSP). Experiments give the relaxation values for both formulations. An alternate formulation is proposed, with more constraints but experimentally competitive. Then, binary encoding is explored to improve the linear relaxation.

2 - Arc Flow Formulation for the Robust Parallel Machine Scheduling Problem

Helioisa Vasques da Silva, Alberto Locatelli, Silvio Alexandre de Araujo, Manuel Iori

In the Parallel Machine Scheduling Problem (PMS) with makespan minimization, we are given a set of jobs with processing times and a set of identical parallel machines. Each machine processes at most one job at a time, and preemption is not allowed. The problem consists of scheduling all jobs into the machines, minimizing the maximum completion time of the jobs. Considering the fact that the processing times of the jobs are not exactly known in advance but typically belong to a

given interval, in this work, we address a variant of the PMS designed to represent data uncertainties affecting the processing times. The resulting Robust Parallel Machine Scheduling Problem (RPMS) uses a budgeted uncertainty set, where a limit is imposed on the number of jobs whose processing time can change from their nominal value on each machine. Starting from the Dynamic Programming (DP) algorithm for the 0-1 Robust Knapsack Problem, we introduce an arc flow formulation based on the DP algorithm. To assess the efficiency of the model, we have tested it on a set of instances from the literature, identifying the methods that yield the best results.

3 - A branch-and-price algorithm for scheduling continuous steel annealing lines

Sebastian Wegel

Continuous annealing is a core process in steel cold-rolling facilities, where order-specific pieces of flat steel, wound up to coils, are processed through an annealing furnace to achieve defined material properties. To enable a continuous process, the coils are welded together before entering the line. Whenever two consecutive coils are incompatible, a special dummy coil called stringer is used to connect them, which reduces efficiency and adds costs and emissions. We consider the scheduling of coils with specific due dates and alternative order-specific processing modes on parallel heterogeneous lines. The problem is to simultaneously assign coils to lines and sequence them on these lines with a defined processing mode with adherence to tardiness constraints while minimizing the number of stringers needed and the associated energy consumption. To address this problem, we formulate a mixed-integer linear program and propose a branch-and-price algorithm based on a Dantzig-Wolfe decomposition by lines to solve it. The pricing subproblems are solved using a labeling algorithm. The approach is implemented using the SCIP framework. We present the underlying problem decomposition, implementation, and some first numerical results using a heuristic and a state-of-the-art commercial solver as a benchmark.

4 - Feature selection for new product line design with economies of scale

Shaghayegh Ramezanpour Shalmani, Laurent Alfandari, Sara Rezaee Vessal

Feature selection across different versions of a product, to create a sufficient level of differentiation and yet satisfy customers' expectations, is one of the complex decisions that companies need to make frequently. In this research, using Mixed-Integer Linear Programming, we decide on the levels of each feature in the various versions of the product line, in the presence of discount on the purchase price of initial components as a function of the purchased quantity. We study the trade-off between the cost of the products, and customers' utility based on a First Choice model, to maximize the firms' profit. Since the problem can easily get intractable with an increase in its size, we propose various families of valid cuts to strengthen the model and accelerate solving. Conducting extensive numerical experiments, we provide managerial insights to help manufacturers' designing their products. We also analyze the impact of varying the purchasing discount rate of components, the degree of market competitiveness, and the degree of heterogeneity of customers' preferences on the optimal design choices. The impact of these variations is measured in terms of manufacturer's profit, intensity of economies of scale, and the level of homogeneity vs. heterogeneity of the different versions of the product line.

Retail Optimization

Stream: Retail Operations

Invited session

Chair: [Naoko Miyashita](#)

1 - Integrated inventory-control method for multiple sales-promotion types

Naoko Miyashita, Junko Hosoda, Takahiro Nishikawa, Akira Koyama

In retail, sales promotion plays a key role in gaining a competitive advantage. Products are often sold by combining multiple sales-promotion types, e.g., regular sales, discounts, and coupons. Therefore, inventory control for multiple sales-promotion types has been attracting interest. Each promotion type for a product differs in its demands' distribution and target service level. The inventory-policy variables for each promotion type are typically optimized individually to replenish the inventory separately. However, this separation method risks shortage and excess stock since the inventory is not shared among the promotion types. An integrated inventory-control method of the (s, S) policy for multiple sales-promotion types is proposed. The policy variables are calculated as follows. The required inventory is first calculated for each inventory type such as safe stock, pipeline stock and cycle stock. The policy variables are then calculated by summing the required inventory of each inventory type for all promotion types. This enables the sharing of inventory among promotion types and satisfies the target service level of each type, reducing shortages. By omitting the cycle stock while replenishing for promotion types with large uncertainty in demand, the excess stock due to forecast error is reduced. The results of numerical experiments indicate that the proposed method reduces shortage and excess stock compared with the conventional separation method.

2 - Enhancing Shopping Centre Profitability through Optimized Tenant Mix and Synergistic Placement

Grace Maureira-Alegría, F.-Javier Heredia

The strategic allocation of tenants within shopping centers, known as "tenant mix," is crucial for enhancing profitability in the retail sector. This research delves into creating an ideal combination of retail categories and their placement to boost rental income, a primary financial source for mall operators. Utilizing integer linear programming, we propose a model that integrates the concept of tenant synergy at its core—a critical yet underexplored aspect in the literature. This model includes constraints based on the total leasable space available and the strategic distribution of store units. Drawing upon a dataset from 27 shopping centers in Spain, we construct a regression model to estimate base rent, positioning it as the critical component of our objective function to maximize rental income. Additionally, this objective function features a synergy-based scoring system as an extra component, designed to enhance sales revenues and create a balanced retail environment through strategic tenant placement. The effectiveness of our model is demonstrated through several case studies, highlighting its potential to increase rental income and sales. Our findings offer mall operators a practical tool to optimize vacant spaces, facilitating strategic decision-making in the retail industry. Acknowledgments: This research was partially supported by ANID (Chile) through Ph.D. scholarship #72190065 and AGAUR through Ph.D. project #2019DI098.

3 - Predicting Electronic Invoice Consumer Product Brand Choices Using Deep Learning Methods

Chih-Chou Chiu, Ling-Jing Kao

Recent technological advancements have significantly impacted consumer behavior and the operational models of physical retail businesses. With the rise of data science and artificial intelligence, scholars are increasingly utilizing deep learning methods to predict consumer behavior in traditional channels. This study addresses a gap in the literature by focusing on predicting consumer brand choices based on electronic uniform invoice data. Specifically, it examines consumers purchasing cigarette brands in physical channels. Using Long Short-Term Memory (LSTM), the study predicts the cigarette brands consumers with smoking habits might choose in their next purchase. Five machine learning approaches are also employed for comparison. The results indicate that factors such as consumption time, location, and product prices significantly influence prediction accuracy. LSTM outperforms other models, demonstrating superior performance in predicting consumer brand choices. These findings provide valuable insights for channel operators to optimize marketing strategies, product offerings,

and operational efficiency, ultimately enhancing market competitiveness. This study offers practical implications for cigarette companies and retailers in understanding and satisfying consumer needs in physical channels using electronic invoice data.

■ WD-51

Wednesday, 14:30-16:00 - Room: M5 (building: 101)

Transit

Stream: Public Transport Optimization

Invited session

Chair: Michel Bierlaire

1 - Integrating Heterogeneous Multi-Depot Vehicle Scheduling and Public Transit Assignment for Enhanced Transit Operations: A Simulation-based Framework

Prateek Agarwal, Prashanth Kokkonda, Tarun Rambha

Public transit agencies make ad-hoc supply-side changes with an aim to improve service quality. However, the benefits of these supply-side improvements heavily depend on the complex behaviour of users, who typically prioritize multiple criteria, such as travel times and the number of transfers while choosing routes. Agencies, on the other hand, decide trip-to-vehicle assignments (Multi-Depot Vehicle Scheduling, MDVS). However, these decisions should (1) account for temporal and spatial variation in demand and (2) consider the changes in passenger choices they may trigger. The study proposes a local search framework that assigns a heterogeneous fleet to trips (HMDVS) so that the resulting capacity on the route is commensurate with the demand for travellers along routes. We assess user responsiveness via a simulation-agent-based public transit assignment (PTA) that predicts travellers' route choices based on transit schedule and capacity constraints. Our local search operators are designed to effectively capture the user sensitivity to supply perturbations, leveraging the interaction between PTA and HMDVS. Analysis on real-world transit networks such as Santa Barbara, Columbus, and Surat show that our PTA framework can simulate millions of passengers in a few hours. Additionally, we observe savings of up to 10% in operational costs on switching from a homogeneous to a heterogeneous fleet.

2 - Modal split on a single edge to minimize multiple objectives

Sven Jäger, Anita Schöbel

When a traffic planner plans the offer of different transport modes, she aims at minimizing simultaneously the total travel time, the total operating cost, and the total CO2 emission. We consider the setting of two cities with a fixed travel demand that can be connected by different transport modes such as a highway for cars, a tram line, and regional trains. The contribution of each mode to the three objective functions depends on the number of passengers using that mode and on the service to be set up to serve them. We are interested in Pareto-optimal modal splits, which cannot be improved in one objective without degrading another objective.

Motivated by this application, we study general tri-criteria problems over a simplex (representing possible modal splits of the total demand), where we assume that all objective functions are separable over the variables. In the case that all objectives are linear, the Pareto-optimal set is simply the convex hull of all Pareto-optimal pure modes, which is a face of the simplex. We study the structure of the solution set for more general objective functions, such as convex differentiable or piecewise constant objective functions in order to develop tailored algorithmic approaches.

3 - Welfare maximization for a user-centric transportation system

Meritxell Pacheco Paneque, Shadi Sharif Azadeh, Michel Bierlaire

Despite their relevance in policy evaluation, social impacts and socio-demographic distributional effects of transportation systems have been less addressed than economic or environmental considerations. This lack of social indicators mainly has to do with the way the demand is modeled for policy analysis (e.g., by assuming an aggregate representation and/or constant demand elasticities). In this research, we derive a tractable measure of social welfare that revolves around the notion of expected maximum utility as given by discrete choice models based on the random utility principle. In addition, their disaggregate nature allows to carry out distributional analyses for different groups with similar socioeconomic characteristics. To illustrate this methodology, we consider an urban multi-modal system where both private and public transport modes are managed by a single planning authority that has control of the related decisions (e.g., price, frequency) and the welfare measure is to be maximized. The optimization problem governing these decisions is constructed using the choice-based optimization framework previously introduced by the authors, in which a linear representation of discrete choice models is embedded in a mixed-integer linear programming formulation to capture the interaction between the expected demand and the supply-related decisions. We propose a semi-synthetic case study on the introduction of a road toll in a corridor connecting two cities in Switzerland.

1 - Optimizing workspace scheduling for shipyard manufacturing under additional resource input consideration

Hyung Joo Cha, Seokhyun Chung, Taesu Cheong

In this presentation, we present a novel scheduling algorithm tailored specifically for the shipbuilding industry, with a key focus on integrating additional resource input to potentially minimize makespan. While prior research has addressed various facets of shipyard scheduling, most efforts have centered on optimizing schedules based solely on existing resource capacities, often neglecting the critical issue of alleviating bottlenecks caused by resource limitations. Our research fills this gap by introducing a novel mathematical model designed to augment existing shipbuilding scheduling systems. This model strategically incorporates the option of supplementing resources to alleviate bottlenecks, all while accounting for the associated acquisition costs. Complementing this mathematical framework, we developed a heuristic algorithm meticulously crafted to enhance efficiency. Through extensive computational experiments, we demonstrate the efficacy and robustness of our proposed approach.

2 - A review of order batching optimization problems

Eduardo G. Pardo, Sergio Gil-Borras

There is a family of related optimization problems, commonly denoted as Order Batching Problems, which are tackled as part of the supply chain management. This family, groups those problems consisting in the optimization of the picking process in a warehouse, when the picking policy follows a batching strategy. The batching strategy consists of grouping the items into batches before starting the picking process. The picking of the items within the same batch is then performed on

a single picking route and all items in the batch are picked together. Tackling an Order Batching Problem usually involves solving several activities, necessary to perform the picking process, such as: batching, routing, assigning, sequencing, or waiting, among others. In this review we focus on manual picking systems performed in rectangular-shaped warehouses, which is probably the most common warehouse configuration in the literature. We review and classify the problems in the literature on a new taxonomy, examining the most outstanding heuristic and metaheuristics algorithms proposed to tackle the different tasks of the problem. Finally, we outline future research directions related to the studied topic.

3 - Optimizing Refinery Maintenance Planning Processes with Three-step Algorithm Approach

Melike Kamuran Onat, Ocan Sahin, Barış Yıldız, Büşra Aydın, Çağrı Bahadır, Berker Günay, Mustafa Oktay Samur

Petroleum refineries are intricate industrial facilities, and effective management of maintenance and repair activities is crucial for uninterrupted production processes. The inter-dependency of maintenance tasks and their predetermined start and end dates is the focus of this study, and the use case is selected from an oil refinery. An optimization model is proposed to minimize the inefficiencies in the form of idle machinery, underutilized teams, and relocation of maintenance technicians between the given tasks. A three-step algorithmic approach is suggested. Firstly, an unconstrained binary knapsack model is employed to reduce the problem size. Secondly, a constrained knapsack problem is solved via mathematical programming to determine maintenance schedules. Finally, a Time-Expanded Network Flow Algorithm is used to assign maintenance teams to the scheduled maintenance tasks, minimizing the number of workers used to execute the scheduled maintenance tasks. The proposed algorithm will not only shorten the time required for planning experts to create a weekly plan but also enhance the utilization of technicians. By streamlining the maintenance and repair processes, the algorithm aims to optimize resource allocation and improve overall operational efficiency in petroleum refineries.

1 - Integrating group heterogeneity in assessing carbon performance of water companies: a case study for england and wales

Maria Molinos-senante, Trinidad Gomez, Rafael Caballero, Ramon Sala-Garrido, Alexandros Maziotis

One of the main challenges that water companies face is to reduce carbon footprint in their transition to carbon neutrality. Past research assessing carbon performance of water companies have mostly ignored heterogeneity among the water companies evaluated. To overcome this limitation, this study employs a parametric metafrontier approach to assess and compare carbon performance of a sample of English and Welsh water companies, embracing water and sewerage companies (WaSCs) and water only companies (WoCs). This method allows for a comparison of the carbon performance of these two types of companies and analyses the impact of environmental variables on their performance. It was evidenced that water treatment complexity, main source of raw water and population density significantly influence carbon performance of water companies. WaSCs were found to be more carbon efficient than WoCs. Moreover, on average WaSCs have improved carbon productivity across years (2011-2020) whereas WoCs have worsened it. The insights gained from this study are highly significant for policymakers focused on transitioning the water industry towards net-zero carbon emissions.

2 - A Bi-Level Optimization Model for Congestion and Emission Control in Transportation Networks

Anna Laura Pala, Giuseppe Stecca

Congestion addressing issue is of utmost importance to ensure the sustainable development of urban conglomerates, particularly in light of governmental initiatives aimed at regulating emissions. Congestion mitigation through resource optimization, not only enhances commuter quality of life, but also alleviates delays and reduces operational cost for carriers. This research introduces a novel bi-level model aimed at addressing congestion and emissions control in transportation networks. At the first level, acting as authority, our model aims to mitigate congestion and reduce emissions. By analysing traffic flows and assessing congestion levels on arcs and routes, we impose a crossing cost proportional to the degree of arc saturation, thereby discouraging congestion buildup while simultaneously penalizing emissions to promote environmental sustainability. At the second level, coalitions make decisions based on cost minimization. Specifically, the follower's problem is presented as a freight forwarding issue, in which the model enables transshipments between vehicles, implicitly allowing coalition formation and promoting a collaborative approach. This model serves as decision support, offering a comprehensive approach to congestion and emissions management in transportation systems. The case study is related to CNMOST PNRR spoke 7 research program.

3 - On Carbon Tax Effectiveness in Inducing a Clean Technology Transition: An Evaluation Based on Optimal Strategic Capacity Planning

Jorge Weston

In this work we study how carbon tax induces a transition to cleaner production under different types of technologies and different demands over a planning horizon. To determine the effectiveness of carbon tax we propose a model based on strategic capacity production planning under carbon taxes. We also present different performance measures to quantify the effectiveness of carbon taxes. The model used is formulated as a mixed integer linear problem (MILP) and consider elements that previous works have not jointly studied, such as machine replacement, workforce planning, and maintenance; elements that are relevant when studying the technological transition. The effectiveness measures proposed in this works, consider levels of clean production and periods to reach a full technological transition. Our computational experiments, based on a real case, have shown that in the absence of carbon taxes, a firm has no incentive to transition to clean technology. Still, the effectiveness of carbon taxes depends on the characteristics of the technology available for the production process and the magnitude of the demand. Finally, we present managerial insights aimed at both companies and the environmental authority to help the planning for a transition to clean technology.

and costly process subject to many constraints. Consequently, infrastructure decisions must be strategically planned over time to maximize passenger benefits.

This research introduces a novel model aimed at optimizing the deployment of infrastructure upgrades in a railway network over a given planning horizon. We propose a Mixed Integer Linear Programming formulation based on the Periodic Event Scheduling Problem formulation for cyclic timetabling. Furthermore, we develop heuristics to tackle this new problem and its operational requirements. We present results on a set of real-life instances from the Netherlands.

2 - Timetable-based network capacity assessment

Franziska Theurich, Sara Comelli, Cédric Kekes, Karl Nachtigall, Norman Weik

In project "Network Capacity" we develop an approach allowing to compute the residual freight capacity for a given passenger timetable, considering freight traffic demand while maintaining punctuality and reliability in operations. Since timetable-based capacity assessment suffers from fluctuating freight traffic demand, we use pre-constructed slots on net segments which will be combined to train paths as the basis of our model. The approach consists of two parts, timetabling and delay prognosis, which are combined to an integrated planning framework. In the timetabling part, we solve a Multi Commodity Flow Problem to predict the required number of slots on network segments. Subsequently, we construct (possible overlapping) slots for freight traffic in the passenger timetable using mathematical optimization techniques such as Branch-and-Price. These slots are the basis for routing freight traffic demand based on a MIP-based slot allocation. In detail, slots are selected and connected to build up conflict-free trains paths. In the delay prognosis part, a stochastic (max,+)-approach is used to assess the reliability of the timetable on the network level. It allows to calculate the delay distribution for each train and every infrastructure element and to assess timetable stability by suitable network performance metrics. With this approach, network capacity can be assessed by scaling the demand up to the maximum that can be reliably satisfied.

3 - A petri net based binary search algorithm to assess feasibility of operational concepts for railway networks.

Christopher Szymula, Nikola Bešinović, Karl Nachtigall

Operational concepts i. e. service networks with macroscopic timetables are an essential railway planning tool and are used for various tasks such as capacity assessment or demand modelling in strategic and tactical planning stages. However, it is crucial to ensure the feasibility of such concepts as they form the high-level base for the timetables of the following planning stages, which need to ensure conflict-free railway operations. Providing feasible concepts is particularly difficult in large railway networks, where numerous and complex interdependencies exist. We therefore propose a petri net based binary search algorithm to determine the feasibility of operational concepts in railway networks. There, the petri net based formulation is used to assess the networks operational period by determining the cycle mean. The minimal cycle mean i. e. the lowest operational period is determined by applying the petri net formulation within a binary search algorithm. The obtained approach determines the lowest operational period in a timely manner. It can thus be used as a lower bound method for constructive capacity assessment algorithms or for the evaluation of operational concepts in the strategic and tactical planning stages. The approach further allows to derive additional information on the critical processes and thus provides a starting point to further concept improvements.

1 - Tactical transportation planning for a Norwegian aluminium producer

Peter Schütz, Julia Rudby, Kristoffer Tufte-Johnsen

We study the tactical transportation planning problem of a Norwegian aluminium producer. Today, products are shipped from the production plants in Norway to customers in Europe using a combination of maritime and land-based transportation. On the first leg from the production plants to terminals on continent, products are shipped using vessels on a fixed, weekly schedule. From the terminals, products are transported by truck to the customers when needed. Each customer is served through a dedicated terminal. The current planning process has resulted in challenges as vessel capacities are not sufficiently accounted for, often resulting in the need to manually reassign shipments from dedicated routes to alternative routes. We present a mathematical model for supporting decision-makers when setting up the transportation plan. The goal is to minimize the total transportation costs while ensuring that all customers are served within the delivery deadline. We further analyze the benefits of changing the current system with dedicated terminals. The analysis intends to provide insights regarding the interplay between flexibility in the transportation system, transportation costs, vessel capacity utilization, and system complexity

2 - Navigating Arctic Waters: A Risk-Averse Stochastic Shortest Path Problem

Gleb Sibul, Peter Schütz, Kjetil Fagerholt

Rapid global warming and declining ice are making Arctic routes more navigable. These routes can reduce shipping time between Europe and Asia, offering economic and environmental benefits by lowering fuel consumption and associated emissions. The main uncertainty in the planning of the routes stems from dynamically changing ice conditions. In this paper, we formulate a risk-averse stochastic shortest path problem for a vessel sailing in the Arctic Ocean. It estimates an optimal vessel path before the departure, without knowing the exact realization of ice conditions. The objective is to minimize total travel time under conditional value at risk, considering the performance in the worst scenarios. The sailing speed (and hence the travel time) depends on the ice conditions, where a ship can sail at normal service speed in ice-free water, while the speed must be decreased in unfavorable ice conditions. The model is tested on historical and projected ice data to estimate transit routes between Europe and Asia via the Arctic Ocean. We are interested in obtaining estimates of travel times between Europe and Asia and evaluating possible delays to gain insights into the future of Arctic Shipping.

3 - Traffic rerouting under uncertainty

Oskar Eikenbroek, Ricardo de la Paz Guala

Travel demand management measures providing personalized route advice to receptive road users are potentially powerful in redistributing traffic for the benefit of network performance, typically expressed using indicators on efficiency, safety, emissions and equity. With the well-known trade-off between individual and societal objectives, system-beneficial route advice may involve a detour compared to the habitual choice. Sustained effects however can only be achieved if travelers (incidentally) comply with such advice. Real-world experiments show that travelers can be persuaded or nudged to do so provided that the suggested detour is bounded and acceptable. Determining the system optimal advice while meeting user constraints is a difficult task since travel times depend on the compliance and the potential re-routing behavior of all travelers, which are subject to uncertainty when the advice is given. In this research, we formulate an optimization problem with equilibrium constraints determining the best possible advice in terms of network performance while explicitly accounting for compliance rates, different perceptions of road users and variations in travel times. We use techniques from variational analysis to develop a numerical method to solve the problem. Results reveal that it is key to account for uncertainties in travel times to prevent negative experiences with social route advice and to assure that intended effects are achieved.

4 - Production Network Design under Supply Uncertainty

Michel Fender, Nadia Jaoui, Nizar El Hachemi, Walid Klihi

Our research addresses a production network design problem involving strategic decisions related to selecting production site locations and their capacities, choosing suppliers, and sizing an internal fleet of vehicles and/or engaging external transportation providers. The problem also considers tactical decisions regarding flows between origin-destination pairs, produced quantities, and inventory levels. These decisions are made within a dynamic environment considering uncertainty in suppliers and production capacities, as well as the availability of transportation vehicles. The problem's structure allows us to model it as a multi-stage stochastic model. However, we approximate it as a two-stage model where strategic decisions are made at the first stage, while tactical ones are set as second-stage decisions. To solve various instances of our problem, we assess the efficiency of three resolution methods: Cplex's default branch-and-cut algorithm, Cplex's Benders decomposition, and partial Benders decomposition. Next, we demonstrate the relevance of integrating the three strategic decisions instead of making them separately and study the impact of different degrees of uncertainty on these decisions. Our findings justify that partial Benders decomposition produces high-quality solutions while achieving computational efficiency, highlighting the suitability of the stochastic model and the resolution approach for dealing with practical supply chain applications.

Last mile delivery with drones

Stream: Transportation

Invited session

Chair: Giovanni Campuzano

1 - Collision-free Trajectory Planning for Drones with Velocity Dependent Energy Consumption and Moving Piggyback Vehicles

Christin Münch, Alf Kimms

When drones are to be used in last-mile delivery, the limited drone flight range poses a major challenge. To mitigate this drawback, we allow the drone to be launched and recovered from moving trucks. Further, we allow for variable drone velocities, as the energy consumption and therefore the drone flight range is heavily dependent on its velocity. We consider one truck that launches the drone, and another one that recovers it. Both trucks drive along streets, and the launching and recovery can take place on any position along these streets. To synchronize the trucks with the drone, the departure times of both trucks are determined as well. Further, we incorporate obstacles that the drone must avoid, which may represent buildings, mountains, no-fly zones, or areas with a high probability of the drone being captured. We take on a geometric approach where the drone operates in the Euclidean space, and to the best of our knowledge, such a geometric viewpoint has not yet been adopted in a MILP for truck-drone last-mile delivery. Our MILP determines a collision-free trajectory for the drone in an environment with obstacles where the drone is launched and recovered by moving vehicles, such that the parcel is delivered as early as possible. The results of our extensive computational study, including the evaluation of three valid inequalities, prove the usefulness of our model, as even large instances with up to 300 obstacles can be solved within reasonable computation time.

2 - An exact method for the Single Drone-Truck Routing Problem

Jahir Llagas, Marcel Turkensteen, Sanne Wøhlk

In urban logistics, the integration of drones with traditional delivery methods presents a promising avenue for improving efficiency and sustainability. This study addresses the optimization of last-mile deliveries by a single drone-truck system. Similar to the vehicle routing problem (VRP), the objective is to minimize travel cost of the travel time while serving all clients exactly once. The vehicle routing problem with drones (VRPD) presents the drone as an additional delivery vehicle that the truck can pick up and transport. This problem involves

a network composed of clients, a depot, and dock hubs. The drone can take off from the truck at any vertex, visit at most as many clients as the number of its compartments, and must land at a dock hub, where the truck can pick it up again. Moreover, the drone's battery capacity must be considered on each trip. In this project, we will increase the drone's autonomy by allowing it to visit dock hubs as battery swapping points during a trip (increasing its driving range) and by including cross-docking. The cross-docking process allows the truck to leave products at the dock hubs, where the drone will visit, pick up the products, and start a new trip. We propose an exact approach to solving the problem and present preliminary results.

3 - Application of Genetic Network Programming to optimize logistics services in mountain areas using drones

Alessia Grosso, Caterina Caramuta, Giovanni Longo

In recent years, an increasing number of companies have been introducing drones into the transport sector, mainly to cope with last-mile distribution issues, being these means of transport more cost effective, sustainable and efficient than traditional modes. Notably, their use in remoted areas can increase accessibility and provide support in case of emergency. Existing research studies mainly focus on drone components and on routing optimization problems, but there seems to be a lack of papers dealing with the design of distribution chains implementing drones for last-mile logistics services. This research proposes an application of genetic network programming to optimize the logistics network configuration, with the aim of defining the optimal combination of transport modes serving the implementation of drones in the last-mile distribution. In particular, a multi-criteria method is used to evaluate the fitness of the candidate solutions by combining environmental impacts, transportation performances and costs. Moreover, an ad-hoc crossover operator is developed to preserve the most promising structures during the evolution process. The methodology has been tested through an application to a case study in a mountain area in the North-East of Italy.

4 - Optimizing Last-Mile Logistics: Analyzing Customer-Centric Truck-and-Drone Delivery Systems

Giovanni Campuzano, Alan Osorio-Mora, Eduardo Lalla-Ruiz, Martijn Mes, Paolo Toth

Addressing transportation problems with customer-centric objective functions has become essential for last-mile service providers seeking to enhance service quality, cultivate customer loyalty, and strategically position themselves in the market. These problems have been getting more and more attention from service providers and have shown substantial benefits in markets with large volumes of deliveries per day, such as the last mile. In this paper, we study two truck-and-drone delivery systems that minimize the total waiting time of customers. To study realistic scenarios, we incorporate the interdependencies of asymmetric transportation times, variable drone speeds, weather conditions, energy consumption, and time windows. We formulate these transportation problems as Mixed Integer Linear Programs (MILPs). Furthermore, we propose a Simulated Annealing metaheuristic framework with Local Search procedures (SA-LS) with a cutoff mechanism to avoid large computational times in high-temperature stages. In the experiments, we provide insights into the benefits of addressing customer satisfaction for truck-and-drone last-mile delivery systems. Accordingly, the results show that even though the latency and makespan are time-related objective functions, minimizing the latency does not directly minimize the makespan, and vice versa. Moreover, enabling the drone to fly at slower speed levels generates significant reductions in the total customer waiting times.

1 - Time-to-build, regulation, and investment

Haejun Jeon

This study investigates the effects of uncertainty in time-to-build and regulation, which hinders immediate revenue generation after investment, on a firm's optimal investment decision. We show that in the absence of regulation, uncertainty in time-to-build always accelerates investment and enhances firm value. We also show that in the absence of time-to-build, uncertainty in regulation can mitigate the distortion of investment induced by regulation. Furthermore, in the presence of both time-to-build and regulation, there can exist harmless regulation that does not induce any distortion in the investment decision and does not harm firm value. Lastly, in the presence of both time-to-build and regulation, not only uncertainty in time-to-build but also its presence can accelerate investment.

2 - Investment, partial irreversibility, and competition

Takashi Shibata, Michi Nishihara, Yuan Tian

This study considers the optimal investment timing decision when the investment is not completely irreversible in a competitive market. As shown in Section 8.2 of Dixit and Pindyck (1994), the optimal investment decision is independent of the degree of competition when the investment is completely irreversible. This study finds that the optimal investment decision depends on the degree of competition when the investment is not completely irreversible. As an extreme case, if the competition is strongly intense, the firm never invests. The weaker the competition, the later the investment is exercised.

3 - Generalized Optimal Stopping for Decision Making in Energy Markets

Frank Heinz, Reinhard Madlener

This article presents a generalized method for multi-dimensional optimal stopping, tailored to problems that arise in electricity markets, when addressing decisions under uncertainty. Electricity markets are highly transparent, and considerable research is available that is dealing with the impact of the ongoing energy transition. However, this class of problems does not fit well to established methods for optimal stopping, and therefore, we propose an alternative, generalized approach. We derive a general form of the Hamilton-Jacobi-Bellman equation and set up an example which represents the retrofit of an electrolyzer to an offshore wind farm under the conditions of a transitioning day-ahead market for electricity. We demonstrate the functionality of this approach by solving the optimal stopping problem numerically and show that the method supports decision making well on such an irreversible investment under uncertainty.

4 - Fuzzy Real Options and Game Theory Approach in M&A Pricing Issue

Qiyuan Dai

In today's business landscape, mergers and acquisitions (M&A) are a crucial strategy for growth and development. However, M&A deals often fail due to discrepancies in valuation. To address this issue, this paper aims to present a unique approach to estimating M&A prices by combining fuzzy real options methodology and game theory. By calculating the sum of a company's intrinsic value and M&A incremental value with fuzzy real options, we arrive at an M&A price. However, we find that this price can be influenced by the negotiation process. To determine the final target price during bargaining, the game theory is employed. Our study applies this method to a real case and results show a range of M&A prices that closely match the actual transaction price. This pricing methodology has practical value for corporate decision-making and is particularly relevant in today's competitive and uncertain market environment.

1 - Online Restaurant Meal Delivery Problem: Order Bundling and Fair Assignment

Ke Fang, Ahmed Kheiri, Christopher Kirkbride

Online food ordering is well-developed nowadays, with many people choosing to order their meal online and waiting at home instead of going to a restaurant. We consider a dynamic online restaurant meal delivery problem (ORMDP) where a pool of drivers deliver food from multiple restaurants to ordering customers. The objectives are to reduce both delivery delays and unfairness for drivers to satisfy those two main stakeholders in the meal delivery process. In practice, order delays increase significantly when the demand for orders is high relative to the number of available drivers. To address this issue, we consider the ORMDP as two sub-problems, order bundling and order assignment. First, we implement a policy-based order bundling algorithm that gather orders into groups within drivers' capacity. Second, we propose an order assignment algorithm to allocate the groups to drivers considering both delay reduction and fairness to drivers. In order to enhance realism, we emulate the behavior of drivers as they await assignments by employing an Iterative K-means Clustering approach (IKC). This method entails clustering proximate restaurants into zones, from which drivers opt for selections in accordance with probability distributions. Finally, we developed a discrete-time simulation model to test our methods using public data. The experimental results show that order bundling and fair assignment can effectively improve the delivery service in ORMDP.

2 - A Novel Instance Generator for Simulating Middle-Mile Logistics Networks

Ayman Lotfi, Matteo Petris, Bruno De Backer, Thibaut Cuvelier, Claudia Archetti

To tackle the challenge of optimizing middle-mile logistics, the crucial link between warehouses and final deliveries, we introduce a novel instance generator that aims to create a rich and adaptable dataset of diverse instances to empower researchers and developers. The instance defines a logistics network with hubs, vehicles, routes, lines, and rotations. Additionally, it specifies a list of shipments that need to be transported through this network. To customize the instance, the user can adjust various parameters, such as the number of hubs, density of the space graphs, distribution of shipment weights, or the maximum number of vehicles. The generator reflects real-world complexities through variations in network size and structure. We developed a random graph generator to mimic real-world middle mile networks, by generating space graphs for hubs. Subsequently, lines and routes are randomly constructed on the generated space graphs, while adhering to user-defined constraints. The tool is in the form of an optimized C++ library that enables the generation of instances with a large number of hubs and shipments. It offers the immense potential for advancing middle-mile logistics optimization by providing a comprehensive and adaptable dataset for benchmarking optimization approaches, training machine learning models, and analyzing the impact of network configurations and shipments characteristics on overall efficiency.

3 - Logistics Concept Design for a Battery Pack Production Initiative

Bilgenur Erdogan, Quang-Vinh Dang, Mehrdad Mohammadi, Ivo Adan

This study focuses on designing logistics concepts for an electrical battery pack production setup, inspired by our industry partner. The

production line is composed of automated workstations using industrial fixed robot arms and manual workstations with human operators. Alongside these, autonomous mobile robots (AMRs) and automated guided vehicles (AGVs) are employed to provide material supply and product transportation, respectively. The complexity rises due to the interdependencies among production, material supply, and product transportation. We propose several logistics concepts for this new production setup in order to achieve the best throughput rate while efficiently making use of AGVs and AMRs. Using real-world data from the industry partner, the efficacy of the proposed concepts is illustrated under varying numbers of AGVs, AMRs, and product types through simulation. Numerical results highlight significant changes in the logistics concept choice based on fleet sizes and product types, with extendable implications for high-mix-low-volume production and autonomous manufacturing systems.

1 - Persuasive channel choices - evidence from manager-investor interactions

Anthony Haake, Wolfgang Breuer, Bertram Steininger

This study develops and evaluates a linear optimization model for an optimal channel mix for persuasive communication. It is based on the premise that different disclosure channels induce different processing costs and that a listener's processing capacity for information is constrained. Under these conditions, a persuader benefits from distributing positive and negative information differently to maximize the listener's understanding of the positive and to minimize it for the negative information. By doing so, a persuader effectively increases her persuasive power. We show that our model predicts actual channel choices made by real-world persuaders in the setting of earnings announcements with an out-of-sample approach. Although our model only considers the information's tone and readability, it predicts up to 69% of channel choices correctly, which is statistically significant. We provide robustness tests by assessing the sensitivity of the model's predictive power to changes in numerical assumptions. Additional analysis indicates that persuasive channel choices are a selfish act, as these are predominantly done by firms with low ESG scores and high institutional ownership. A critical discussion of our results and an outlook for future research is provided.

2 - Forecasting M&A shareholder wealth effects to prevent value-destroying deals: Can it be done?

Joao Quariguasi Frota Neto, Konstantinos Bozos, Marie Dutordoir, Konstantinos Nikolopoulos

M&A announcements can result in substantial positive or negative abnormal acquiring-firm stock returns and sizeable associated dollar value gains or losses. Despite the extensive existing M&A literature, whether such losses and gains are predictable remains unknown. Similarly explored are the choices of model for such forecasting. This paper fills this gap. We employ acquirer, target, deal and macroeconomic features commonly used in the literature and test the accuracy of parametric and non-parametric models. As expected, given the high noise-to-ratio inherent of financial forecasting, predictability is low. However, non-parametric models are able to consistently forecast abnormal returns associated with M&As, sometimes surpassing their parametric counterparts. Our analyses of feature importance shows that a handful consistently outweighs the relevance of the remaining subset. We further construct two portfolios of M&As, one containing expected value-generating M&As and another expected value-destroying MA, and show that they are significantly different.

3 - Nonlinear Inferences on European Banking Resilience in Operating Efficiency and Riskiness Around the Financial Crisis

Muktak Tripathi, Madjid Tavana, Tracie Frost, Violeta Cvetkoska

We examine European banks' financial performance and risk management and their trends over the years and across banking characteristics around the financial crisis of 2007-2008. By testing for the linear and nonlinear variations using an exogenous quasi-experiment design, we demonstrate the usefulness of understanding the cause of variations in banks' operating efficiency and riskiness. We adopt the positive theory of capital allocation decisions and risk-taking activities to assess the relationship between banks' efficiency and risk with value creation from intermediation services. First, we peer-benchmark banks' efficiency, using data envelopment analysis, and obtain Fitch risk ratings to test for their yearly and geographical resilience, including linear and nonlinear variations before and after the crisis. Second, we determine bank-specific and industry-specific operational and financial factors, including longitudinal and cross-sectional heterogeneities, that affect European banks' operating efficiency and riskiness. We find that banking efficiency can provide intuition on mitigating excessive investments and risk-taking around the financial crisis. Further, we capture the informational relevance of banking efficiency to third-party agencies in assessing financial strengths and credit risks. Our study provides a foundation to examine variations in European banks' performance and risk realizations, including financial decisions and operating saliency.

Flow shop and single machine scheduling

Stream: Project Management and Scheduling
Invited session

Chair: Elena Renner

1 - An Iterated Greedy Search Procedure for the Distributed Flow Shop Scheduling Problem With Inter-Factory Transportation

Tristan Becker, Janis Sebastian Neufeld, Udo Buscher

Large industrial corporations typically operate a network of several factories, leading to a distributed flow shop scheduling problem for flowline manufacturing processes. This requires assigning jobs to one of multiple distributed factories, each equipped with identical flow shops, where each job must be completed in their designated factory. Our research builds upon the traditional distributed flow shop scheduling problem by including the transport of intermediate goods between factories. This transport can occur after each machine operation, with the transportation times varying based on the distance between the origin and destination factories. The objective is to minimize the maximum makespan across all factories. We propose an iterated greedy search algorithm for the distributed flow shop scheduling problem with inter-factory transportation. Utilizing a graph representation, we have developed a speed-up technique to enhance the search efficiency of the algorithm. Through computational experiments, we demonstrate the efficacy and efficiency of our proposed algorithm. Finally, our research quantifies the value of introducing the possibility of inter-factory transportation. While transportation can potentially delay processing at subsequent machine stages, our findings suggest that this is outweighed by improved machine utilization across factories. Therefore, we observe an enhanced overall efficiency and reduced makespans.

2 - Polynomial-time algorithms for solving timing problems in single-machine rescheduling

Elena Renner, Fabio Salassa, Vincent T'kindt

Rescheduling problems are understood as strategies for updating existing schedules to deal with unexpected changes in the available data. When the change is given by the arrival of a new set of jobs, which are unknown at the time of scheduling, we speak of rescheduling for new orders. In these problems, we consider two sets of jobs, a set of old jobs and a set of new jobs, that must be scheduled together on a single machine. For the set of old jobs, we know the original completion times, that is, the times based on the schedule prior to the insertion of the new jobs. According to these times, additional activities may have been planned and resources made available. Thus, the goal of rescheduling is twofold: to minimize some classical objective function over all jobs, and to minimize the disruption of the original schedule. When the disruption is measured as the total absolute time deviation from the original completion times, the search for optimal solutions raises the problem of determining the insertion of idle time. We provide timing algorithms for solving this problem when the sequence of jobs is known. We show that the proposed algorithms devise the efficient frontier of solutions in polynomial time, and compute an optimal solution in polynomial time, if a disruption threshold is given.

3 - Flow shops with reentry: Total completion time optimal schedules

Nicklas Klein, Michael Pinedo

Flow shops are widely studied machine environments in which all jobs must visit all machines in the same order. While conventional flow shops assume that each job traverses the shop only once, many industrial environments require jobs to pass through the shop multiple times before completion, i.e., after traversing the shop and completing its processing on the last machine, a job must return to the first machine and traverse the shop again until it has completed all its required loops. There are numerous applications, e.g., in semiconductor manufacturing, of such a setting, which is called a flow shop with reentry. The planning problem is to schedule all loops of all jobs while minimizing the total (weighted) completion time. We consider a reentrant flow shop with unit processing times and show that the Least Remaining Loops First (LRL) priority rule minimizes the total completion time. Furthermore, we show that the problem of minimizing the total weighted completion time is NP-hard. For this objective, we show that the Weighted Least Remaining Loops First (WLRL) priority rule has a worst-case performance ratio of about 1.2.

4 - Balancing the average weighted completion times by network design

Antonio Fuduli, Matteo Avolio

We face a single-machine NP-hard scheduling problem, whose objective is to balance the average weighted completion times of two different classes of jobs. Since both the job sets contribute to the same objective function, this problem can be interpreted as a cooperative two-agent scheduling problem, whereas the standard multiagent problems are of the competitive type since each class of job is involved only in optimizing its agent's criterion. Balancing the average completion times of different sets of tasks finds application in many fields, such as in services, for balancing the waiting times of groups of people, and in logistics for balancing the delivery times. To solve this problem, we propose a Lagrangian relaxation approach based on a network flow formulation. A possible bi-criterion extension is also investigated, taking into account the additional objective aimed at minimizing the maximum between the two average weighted completion times. Preliminary numerical results are presented.

Online, Omnichannel, and Pricing

Stream: Retail Operations
Invited session

Chair: Selin Ahipasaoglu

1 - Channel Structure of Online Retail Platforms: Impact of Asymmetric Information and Capacity Constraints

Hasan Shorakaei, Mehmet Bege, Hubert Pun

Problem definition: When selling online, manufacturers can either sell directly to customers through the platform (agency channel), sell their products to the platform (reselling channel), or engage in both channels simultaneously. Manufacturers typically operate with limited production capacity, and this information is often not disclosed to online platforms. **Methodology/results:** Our study develops a screening game framework where the manufacturer has private information about its capacity, and the online platform presents a menu of quantity-price pairs contracts to the manufacturer. The manufacturer then determines the quantity allocated to the reselling channel and to the agency channel. Our finding highlights that the manufacturer is more likely to use both (agency and reselling) channels under the asymmetric information game. We also show that a manufacturer with high capacity benefits from keeping its capacity information private, but a manufacturer with low capacity does not. Furthermore, the platform and the manufacturer may not benefit from the manufacturer having more production capacity. Lastly, we find that if the manufacturer's capacity is sufficiently small, then the platform may be better off not knowing the manufacturer's capacity. **Managerial implications:** Our study offers insights and guidance for manufacturers and online platforms, assisting them in making strategic decisions and navigating the dynamics of information sharing within the online retail.

2 - Assortment Optimization for Fashion Products in Omnichannel Retail

Kritika Swaminathan, Rakesh Venkatasubramony

Forecasting and assortment planning for fashion products have been a challenging area in Operations Research due to different factors, particularly the high percentage of new products that lack any historical sales data. This problem gets more interesting when we incorporate the possibility that products can be ordered and fulfilled in different channels - what we commonly call as Omnichannel. Our study focuses on assortment optimization for products in fashion retail across multiple channels in omnichannel retail. The demand for a combination of attributes is predicted from the existing sales data. Then, from a universe of feasible attribute combinations available across channels - both online and offline - under asymmetric integration, we identify the right mix of products for each channel. We model this decision as a profit maximization function considering predicted sales revenue and the fulfillment cost for different products across multiple channels.

3 - Multi-Purchase Choice Models of a Sequential Purchasing Process

Kexin Lai, Christine Currie, Selin Ahipasaoglu

We consider the situation where customers make a finite sequence of purchase decisions and buy at most one item at each stage, where the sets of items on offer at each stage are disjoint and could be drawn from one or more categories. Our aim is to optimize item prices to maximize overall expected revenue. The basis of the optimization is a choice model that describes how customers make purchase decisions at each stage. We consider two choice models: a single-stage bundle-purchase model (known as the Multi-variate Multinomial Logit model) and a multi-stage sequential purchase model.

Under the single-stage model, we assume that customers form a choice 'bundle' by selecting at most one item from each product set. We model this behavior similarly to the standard multinomial logit model, where customers choose the utility-maximizing bundle. In the multi-stage sequential choice model, customers make a sequence of choices, where the choice made in one stage depends on the choices made in the previous stages. We include product interactions in both models to account for product compatibility.

Similar problems exist in industries such as tourism (travelers visit different destinations), food (restaurants with a rotating selection of specials), retail (stores with rotating inventory), and entertainment (cinemas with rotating films). Our empirical results on real data suggest that models with greater purchase history and information attain higher levels of accuracy.

Port Performance

Stream: OR in Port Operations

Invited session

Chair: *Eduardo Lalla-Ruiz*

Chair: *Rosa G. González-Ramírez*

1 - Comparing the technical efficiency of Chilean and Mexican ports using a stochastic frontier approach

Fabricio Moreno Baca, Ivan Derpich, Claudia Duran, Cristobal Castaneda

In this work, a stochastic cost frontier approach is presented to compare the efficiency of Chilean ports and Mexican ports. This approach is based on the work of several authors, the authors who presented an activity-based operational method for estimate CO2 emissions from container shipping considering repositioning of empty containers. Among other findings they demonstrate that the repositioning Efficient disposal of empty containers can reduce emissions in maritime transport. Based on this background, the following subsection presents an econometric estimation model of CO2 emissions from Chilean and Mexican ports based on in empty containers and the activity of export and import ships. The theoretical framework that supports the work corresponds to the theory of the stochastic frontier of costs introduced by Farrell. The most used frontier models are production and cost models. In this approach, cost frontier models will be applied. The linearized functional form of the Cobb-Douglas production function is the origin of the development of the cost frontier stochastic, which will be used in this work to characterize the technical efficiency of each of the ports. A cost frontier model with panel data will be used. We will use the standard form of the Cobbs-Douglas type cost frontier due to its flexibility to be estimated with a linear function with panel data.

2 - Measuring innovation performance in smart ports under uncertainty: A neutrosophic approach

Antonios Paraskevas, Michael Madas

Smart ports offer a paradigm shift in the constantly evolving marine logistics industry, utilizing cutting-edge technology to enhance efficiency and sustainability. However, accurately measuring innovation performance in these complex and uncertain situations requires a creative and adaptable approach. This study presents a Neutrosophic Approach to measuring innovation success at smart ports while acknowledging and quantifying the inherent uncertainties. Our research incorporates neutrosophic set theory, which is a mathematical framework capable of handling imprecise and indeterminate data. This methodology enables the consideration of unpredictable factors that influence innovation in smart ports, such as technological disruptions, legislative changes, and market dynamics. By employing neutrosophic logic, the model captures the inherent ambiguity and vagueness associated with evaluating innovation performance in this rapidly evolving market. The study approach involves a comprehensive assessment of key performance indicators (KPIs) related to smart port innovation, accounting for both standard metrics and emerging indicators specific to the digitalization and automation of port operations. Neutrosophic language variables are utilized to measure the degree of truth, indeterminacy and falsehood associated with each KPI, facilitating a more nuanced evaluation by providing a comprehensive understanding of innovation success in smart ports amidst uncertainty.

3 - Port fariff considerations

Alejandra Gómez_Padilla, Rosa G. González-Ramírez

In this research we intend to review port tariff literature. In our analysis we consider strategic pricing, infrastructure cost recovery, market conditions and external costs. We are interested in identifying the optimization models and methods used to define tariff structures, and their relation with the strategies, the infrastructure and the market. Strategic

pricing schemes are based on a different tariff between cargo owners due to segment demand or freight traffic. Infrastructure tariffs are usually managed by the port authorities and may be influenced by policies and regulations. The market is influenced by the global supply chain. We expect to identify which are the main elements in literature to decide pricing strategies, infrastructure and the market characteristics as well as the mathematical modeling problems that have been considered.

4 - Performance analysis of liquid bulk terminals

Werner Scheinhardt, Jan-Kees van Ommeren, Debjit Roy

Bulk liquid terminals play a crucial role in timely (un)loading of liquids from tankers and facilitating transport to and from the hinterland via pipelines, trains or trucks. At an import terminal, arriving tankers berth to be unloaded via loading arms and pipelines connected to storage facilities. Whenever the storage is full, the unloading rate essentially decreases to the drain rate of the storage, which increases the sojourn times of tankers considerably. On the other hand, when the storage is empty, the demand on the landside cannot be met and throughput will decrease. The performance of an import terminal serving a single liquid type can be analyzed using feedback fluid queue models, assuming that tankers arrive according to some random process, carrying random amounts of liquid, and experiencing delay when the berth is in use. Importantly, such models explicitly take into account the interaction between tankers and storage reservoir. In this talk we focus on the more complex case with two types of liquid that cannot be mixed, each with their own storage reservoir and tankers, while sharing the same (single) berth. A straightforward fluid queue model is then no longer applicable, but we apply an iterative approximation scheme that performs remarkably well. We present graphs showing how the various parameters influence the behavior of the main performance measures, viz. the expected sojourn times of both types of tankers and the throughputs of both types of liquid.

Complexity and Financial Patterns

Stream: OR in Banking, Finance and Insurance: New Tools for Risk Management

Invited session

Chair: Roy Cerqueti

1 - Volatility of Stock Market Aggregate Volatility (VoV) Forecast Based on Cross-Sectional Intrinsic Entropy's Volatility Estimates

Claudiu Vinte, Marcel Ausloos, Bogdan Iftimie

In the context of index volatility versus the volatility of the entire market, the following question becomes pertinent: Does the market volatility track the index volatility, or is it the other way around? To estimate the market's overall volatility, we employ the cross-sectional intrinsic entropy (CSIE) model as the underlying methodology for tracking the aggregate volatility of all the symbols listed and traded on a given stock market. We investigate the appropriate GARCH models to forecast the variance of market cross-sectional aggregate volatility estimates and the variance of market indices volatility estimates (VoV) forecasting. The CSIE model provides estimates of the daily aggregate volatility for the entire market. Alternatively, index volatility estimates are determined on n-day rolling windows. Therefore, CSIE market volatility estimates are integrated into the research methodology as comparable n-day moving averages. Our study uses historical end-of-day (EOD) data consisting of traded volume, opening, high, low, and closing prices (OHLCV) for all companies listed on the NYSE and NASDAQ and the corresponding market indices, S&P500 and NASDAQ Composite respectively. We conclude that the S&P 500 is not fully representative of the market, and particularly in the periods preceding recessions, it does not capture overall market immanent deep

trends, specifically those revealed through the CSIE market volatility estimator.

2 - Balance in financial signed networks: a new systemic risk measure

Rosanna Grassi, Paolo Bartesaghi, Fernando Diaz-Diaz, Pierpaolo Uberti

Changes in the correlation structures between asset returns strongly reflect the systemic events in the financial context. Commonly, correlation is used in absolute value. However, the question remains as to what information about the systemic risk is contained in the correlation signs, especially when interpreted as the weights of the edges in a signed network. From this perspective, balance theory can provide an interesting insight into catching signals of systemic crises and a meaningful tool to manage portfolio risk. The crucial point is that in balanced systems it is easier to predict the behaviour of a single entity. Hence, the balance contributes to increasing the level of "predictability" of the network behaviour. In a financial context, this is essential in managing risk to face systemic crises. We show how the global balance index can be interpreted as a possible indicator of systemic risk. Moreover, we compare the global balance with some systemic risk indicators from the literature. We focus on the indicators that well-capture the loss of linear independence in the matrix of observations through the analysis of the minimum eigenvalues of the correlation matrix, interpreted as the distance from an appropriate space of rank-defective matrices. Preliminary results are promising and they create a new bridge between systemic risk measures and signed networks.

3 - Are digital entrepreneurial ecosystems resilient to external perturbations? A pre- and post-pandemic empirical analysis

Antonio Iovannella

The complexity of the innovation and entrepreneurship process calls for ever-increasing connectivity. As a result, scholars have begun to focus more on entrepreneurial ecosystems (EE), which emphasise the interconnection of every player in this process. In this vein, external collaborations have been encouraged by the development of digital technology in response to COVID-19. At the same time, the pandemic has posed challenges to the resilience of EE, and the digital dimension may foster resilience from this perspective. In this paper, we use complexity theory and Social Network Analysis to investigate how resilient a digital EE of European startups is to external perturbations both before and after the pandemic. By doing this, we help to clarify the relationship between digital platforms and EE as well as their role in enhancing resilience. Our results show a higher level of robustness to random node removal. Nevertheless, there have been shifts in the paths connecting members as startups diversified their interests across sectors and countries. The new configuration facilitates the shock propagation within the network, leaving room for designing targeted policies and managerial practices to increase the ecosystem resilience. The network's ability to propagate shocks is facilitated by the new arrangement, leaving room for the development of focused policies and managerial techniques that strengthen the resilience of the ecosystem.

4 - FICO Decision Optimizer - Generating predictive models with Action Effect

Claudio Gambella, Livio Bertacco, Sebastien Lannez, Ben Willcocks, Brendan del Favero, Ryan Weber

The FICO Decision Optimizer (DO) application is an optimization software package to perform optimal assignment of treatments to a portfolio of customers. DO leverages optimization algorithms with the goal to empower non-OR professionals with a tool that creates and solves Generalized Assignment Problems, without requiring them to formulate the models. DO considers different kinds of constraints (e.g., budget, ratio) and allows users to generate highly interpretable decision trees. The DO models depend on structural inputs (e.g., portfolio or customer attributes) and uncertain inputs (predictable target values, such as the impact of treatments on customers). While the DO interface enables configuring and editing of the predictive models required to produce the uncertain data, developing Predictive Causal Models usually requires additional tools and knowledge for a Business Analyst. Furthermore, there is inherent historical data bias, because the

historical actions are likely to be targeted on certain segments. Consequently, there may be significant data gaps for some actions. To simplify the user experience, we developed an Action Effect (AE) approach to predict the impact of the treatment assignment on every customer of the portfolio. We present the logic behind the quadratic programming models that create the predictive models. We conclude our presentation with a discussion about the advantages of this methodology over standard unconstrained linear regression.

Heuristics for Vehicle Routing 2

Stream: VeRoLog - Vehicle Routing and Logistics

Invited session

Chair: [Patricia Zech](#)

1 - Matheuristic for Feeder Network Design Problem With Optional Paired Demands and Split Delivery

Anandhu Dileep, Ahmad Hemmati

In this work, we study a complex variant of the feeder network design problem (FNDP) arising in the field of maritime transportation. The problem is about designing routes for ship services between several shipping ports, to deliver cargoes between these ports based on a fixed weekly demand. In many cases, this is done using disjoint networks of ships services, called feeder networks.

Each feeder network is connected to a main port by a long ship service called a mother route. Some of the paired demands are delivered by the mother routes themselves, and the remaining demands using daughter routes, which are shorter ship services that branch off from some of the ports in the mother routes.

In the variant of the FNDP studied, we also allow split deliveries of the demands and the rejection of some of the demands. There are time constraints on the routes and on the travel time for delivery of each cargo. We formulate a mathematical model for the problem and propose a matheuristic framework for obtaining high quality solutions.

2 - Hybrid Randomised and Greedy Technique as a Novel Approach to Solve the Open Vehicle Routing Problem (OVRP)

Abdullah Almouhanna, Hassana Abdullahi, Angel A. Juan

The Open Vehicle Routing Problem (OVRP) is a complex combinatorial optimization challenge with numerous real-world applications in transportation, logistics, and urban planning. The OVRP differs from the Vehicle Routing Problem (VRP) because the vehicles either are not required to return to the depot, or if they are to do so by revisiting the customers in the reverse order. The OVRP is faced by a company which either does not own a vehicle fleet at all, or its vehicle fleet is inappropriate or inadequate to satisfy the demand of its customers. Our approach is based on combination of the Iterated Greedy (IG) with biased randomization technique. The IG has been developed by to solve the Permutation Flowshop Scheduling Problem (PFSP) in order to minimise makespan. It is reasonably simple to implement and parameter free. One of our aim of choosing this method is that, the IG has been applied successfully for some Combinatorial Problems specifically and has been proven to generate high quality solutions. Despite the proven impressive performance of IG, it has not been applied in the OVRP. Biased randomisation technique refers to the utilisation of pseudo-random numbers to generate random outcomes throughout the solution search. By randomizing some steps in a deterministic heuristic, it is transformed into a probabilistic procedure. Then, it can be run multiple times - either in sequential or parallel mode - in order to obtain different outcomes or solutions.

3 - A Metaheuristic Approach for the Meal Delivery Routing Problem

Daniel Giraldo-Herrera, David Álvarez-Martínez

With the exponential growth of e-commerce platforms, fueled by the increasing demand for meal delivery services, delivery efficiency emerges as a pivotal concern for businesses. This paper delves into the Meal Delivery Routing Problem (MDRP) within the realm of e-commerce, addressing the delivery applications, couriers, restaurants, and customers' objectives that often conflict among them. The study focuses on the complexities of last-mile logistics, emphasizing the imperative for a robust solution to achieve operational efficiency, enhance customer satisfaction, promote environmental sustainability, and minimize lost sales. This paper presents a GRASP metaheuristic solution that tackles the MDRP by optimizing courier assignment to orders while accounting for dynamic variables like courier availability, order demands, and geographical considerations. The methodology is validated using real-life scenarios based on data from a delivery app operating in South America. Comparative analyses with a simulation-optimization-based study underscore the efficacy of GRASP in enhancing order fulfillment and routing efficiency, showcasing its strengths across diverse locales such as Sao Paulo (Brazil), Bogota, and Medellin (Colombia). As future research, we propose exploring optimization models geared toward maximizing the welfare of all stakeholders within the meal delivery services system. Such an endeavor aims to foster genuine democratization of delivery services.

4 - Analyzing the Benefits of Node Aggregations in Vehicle Routing Problems

Patricia Zech, Christian Almeder

The constant growth of e-commerce challenges last mile delivery service providers to find cost-efficient route plans that fulfill the demand of thousands of customers daily. To facilitate problem abstraction, a variety of distribution or collection problems as postal delivery or garbage collection are modelled as arc routing problems. Compared to dense urban areas, where an aggregated view on arcs instead of nodes is straight forward for reducing the complexity of the problem, the situation in rural or suburban areas is different. Aggregation of nodes along a long street segment might cause a depletion of the route quality. We are investigating the possibility of various node aggregation heuristics for such situations, which transforms a large-scale vehicle routing problem (VRP) into a smaller capacitated general routing problem (CGRP), where demand might be located on nodes, edges, or arcs. Several mathematical problem formulations for the latter are analyzed and evaluated regarding their solution performance compared to standard VRP models. The goal is to specify the trade-off between the level of aggregation, the loss of solution quality and the decrease in computational time.

1 - The operations of well-being: How operations interacts with happiness, equity, and sustainability

Charles Corbett

What does well-being have to do with operations? Well-being encompasses a lot: Are we happy as individuals? Are groups treated fairly? Is society sustainable? Operations management has many impacts on well-being at each of these levels, some more obvious than others. This talk will offer a wide-ranging exploration of linkages between operations and well-being. It organizes "operations" into five broad areas: pace and productivity, predictability and probability, process and prevention, performance and payment, and pollution and protection. For each of those, it explores what makes individuals (un)happy, what is fair, and what is sustainable. Operations cannot solve all societal problems but the links between quality of operations and quality of life are more numerous and nuanced than we usually realize.

Nina Kajiji
University of Rhode Island, and The NKD Group, Inc.
nina@nkd-group.com

Gerhard-Wilhelm Weber
Poznan University of Technology
gerhard-wilhelm.weber@put.poznan.pl

Track(s): 18

OR in Agriculture and Forestry

LluisM Pla
University of Lleida
Impla@matematica.udl.es

Track(s): 12

OR in Banking, Finance and Insurance: New Tools for Risk Management

Rita D'Ecclesia
Sapienza University of Rome
rita.decclesia@uniroma1.it

Track(s): 2 63

OR in Energy

Luis Baringo
Universidad de Castilla-La Mancha
luis.baringo@uclm.es

Álvaro García-Cerezo
Universidad de Castilla-La Mancha
alvaro.garciacerezo@uclm.es

Track(s): 19 21

OR in Financial and Management Accounting

Matthias Amen
Bielefeld University
matthias.amen@uni-bielefeld.de

Track(s): 59

OR in Health Services (ORAHS)

Roberto Aringhieri
Università degli Studi di Torino
roberto.aringhieri@unito.it

Kris Braekers
Hasselt University
kris.braekers@uhasselt.be

Walter Gutjahr
University of Vienna
walter.gutjahr@univie.ac.at

Patrick Hirsch
University of Natural Resources and Life Sciences, Vienna
patrick.hirsch@boku.ac.at

Melanie Reuter-Oppermann
University of Twente
m.n.reuter-oppermann@utwente.nl

Track(s): 10 15 17

OR in Humanitarian Operations (HOpe)

Douglas Alem
University of Edinburgh
douglas.alem@ed.ac.uk

Tina Wakolbinger
WU (Vienna University of Economics and Business)
tina.wakolbinger@wu.ac.at

Track(s): 21

OR in Port Operations

Rosa G. González-Ramírez
Universidad de Los Andes, Chile
rgonzalez@uandes.cl

Eduardo Lalla-Ruiz
University of Twente
e.a.lalla@utwente.nl

Track(s): 62

OR in Sports

Dries Goossens
Ghent University
dries.goossens@ugent.be

Track(s): 16

OR Journals

Roman Slowinski
Poznan University of Technology
roman.slowinski@cs.put.poznan.pl

Track(s): 8

Plenaries

Track(s): 1

Pricing and Revenue Management

Luce Brotcorne
INRIA
luce.brotcorne@inria.fr

Track(s): 59

Project Management and Scheduling

Erik Demeulemeester
KU Leuven
erik.demeulemeester@kuleuven.be

Joanna Józefowska
Poznan University of Technology
joanna.jozefowska@cs.put.poznan.pl

Track(s): 60

Public Transport Optimization

Dennis Huisman
Erasmus University
huisman@ese.eur.nl

Marie Schmidt
University of Würzburg
marie.schmidt@uni-wuerzburg.de

Track(s): 51 54

Quantum Computing Optimization

Brandon Augustino
Lehigh University
bra216@lehigh.edu

Tamás Terlaky
Lehigh University
terlaky@lehigh.edu

Track(s): 42

Real Option Analysis

Mikael Collan
VATT Institute for Economic
Research
mikael.collan@vatt.fi

Track(s): 57

Recent Advancements in AI

Sureyya Ozogur-Akyuz
Bahcesehir University
sureyya.akyuz@eng.bau.edu.tr

Duygu Üçüncü
Bahcesehir University
duygu.ucuncu@bau.edu.tr

Track(s): 4

Retail Operations

Pedro Amorim
Faculty of Engineering of University
of Porto
amorim.pedro@fe.up.pt

Rob Broekmeulen
TU Eindhoven
r.a.c.m.broekmeulen@tue.nl

Alexander Hübner
Technical University Munich
alexander.huebner@tum.de

Heinrich Kuhn
Catholic University of
Eichstaett-Ingolstadt
heinrich.kuhn@ku.de

Winfried Steiner
Clausthal University of Technology,
Institute of Management and
Economics
winfried.steiner@tu-clausthal.de

Track(s): 50 61

Risk management in finance

Tomáš Tichý
Faculty of Economics,
VSB-Technical University Ostrava
tomas.tichy@vsb.cz

Track(s): 51

Secure & Sustainable Food Supply

Marleen Balvert
Tilburg University
m.balvert@tilburguniversity.edu

J.c. Gerdessen
Wageningen University
joke.vanlemmen@wur.nl

Track(s): 13

Soft OR and Problem Structuring Methods

Irene Pluchinotta
University College London
i.pluchinotta@ucl.ac.uk

Chris Smith
University of Manchester
christopher.smith@manchester.ac.uk

Mike Yearworth
University of Exeter
m.yearworth@exeter.ac.uk

Track(s): 13

Software for Optimization

Timo Berthold
Fair Isaac Deutschland GmbH
timoberthold@fico.com

Robert Luce
Gurobi
luce@gurobi.com

Track(s): 30

Stochastic and Deterministic Global Optimization

Boglárka G.-Tóth
University of Szeged
boglarka@inf.szte.hu

Track(s): 41

Stochastic Modelling

Raik Stolletz
University of Mannheim
stolletz@bwl.uni-mannheim.de

Track(s): 39

Stochastic, Robust and Distributionally Robust Optimization

Milos Kopa
Charles University in Prague, Faculty
of Mathematics and Physics
kopa@karlin.mff.cuni.cz

Francesca Maggioni
University of Bergamo
francesca.maggioni@unibg.it

Track(s): 34 35

Sustainable and Resilient Systems

Lina Kattan
University of Calgary
lkattan@ucalgary.ca

Elise Miller-Hooks
George Mason University
miller@gmu.edu

Hulya Julie Yazici
Florida Gulf Coast University
hyazici@fgcu.edu

Track(s): 53

Sustainable Cities

Virginia Pelleray
Politecnico di Torino
virginia.pelleray@polito.it

Sara Torabi
Politecnico di Torino
sara.torabi@polito.it

Grit Walther
RWTH Aachen University
walther@om.rwth-aachen.de

Track(s): 18

Sustainable Supply Chains

Karsten Kieckhäfer
FernUniversität in Hagen
karsten.kieckhaefer@fernuni-
hagen.de

Track(s): 24

Transportation

Riccardo Rossi
University of Padova
riccardo.rossi@unipd.it

Track(s): 55 56 60

Variational Analysis and Continuous Optimization

Fernando García Castaño
University of Alicante
fernando.gc@ua.es

Abderrahim Hantoute
Universidad de Alicante
hantoute@ua.es

Track(s): 42

Variational Inequalities and Equilibrium Problems: From Theoretical Advances to Real World Applications

Mauro Passacantando
University of Milano-Bicocca
mauro.passacantando@unimib.it

Fabio Raciti
University of Catania
fraciti@dmi.unict.it

Track(s): 43

Vector and Set Optimization

Lidia Huerga
Universidad Nacional de Educación a Distancia, UNED
lhuerga@ind.uned.es

Vicente Novo
Universidad Nacional de Educacion a Distancia
vnovo@ind.uned.es

Miguel Sama
Universidad Nacional de Educación a Distancia, UNED
msama@ind.uned.es

Track(s): 41

VeRoLog - Vehicle Routing and Logistics

Rossana Cavagnini
RWTH Aachen University
cavagnini@dpo.rwth-aachen.de

Roberto Roberti
University of Padova
roberto.roberti@unipd.it

Track(s): 58 64

WISDOM - Women in OR

Paula Carroll
UCD
paula.carroll@ucd.ie

Track(s): 12

SESSION INDEX

Sunday, 16:30-17:30

| | |
|---|---|
| SF-01: Opening Session (Sportshallen (building: 101)) | 3 |
|---|---|

Monday, 8:30-10:00

| | |
|---|----|
| MA-01: Graham Rand (Sportshallen (building: 101)) | 4 |
| MA-02: EDDA (Glassalen (building: 101)) | 4 |
| MA-03: Industrial Optimization (1005 (building: 202)) | 4 |
| MA-04: Recent Methodologies in Explainable AI (XAI) I (1001 (building: 202)) | 5 |
| MA-07: Cutting and Packing 1 - 2D rectangular (1019 (building: 202)) | 6 |
| MA-08: Portfolio optimization and sustainability (1020 (building: 202)) | 6 |
| MA-09: Modelling and Economics of Storage Technologies in Energy Markets (10 (building: 116)) | 7 |
| MA-10: EMS logistics (11 (building: 116)) | 8 |
| MA-11: Choice behavior (12 (building: 116)) | 9 |
| MA-12: Optimization in Agriculture (13 (building: 116)) | 10 |
| MA-13: Supporting Planning and Sustainability (15 (building: 116)) | 10 |
| MA-14: Impacts of transitioning to green gases (16 (building: 116)) | 11 |
| MA-15: Machine learning and game theory in healthcare (18 (building: 116)) | 12 |
| MA-16: OR Education I (19 (building: 116)) | 13 |
| MA-17: Decision support in healthcare (40 (building: 116)) | 13 |
| MA-18: Assessment Methods for Shaping the Green, Inclusive, and Digital Cities I (42 (building: 116)) | 14 |
| MA-19: Learning-assisted Optimization in Energy Problems (44 (building: 116)) | 15 |
| MA-20: Ethics of OR and artificial intelligence (45 (building: 116)) | 15 |
| MA-21: Planning problems in electrical energy systems (49 (building: 116)) | 16 |
| MA-23: Circular Economy, Remanufacturing and Recycling (82 (building: 116)) | 17 |
| MA-24: Sustainable Supply Chain Design (83 (building: 116)) | 18 |
| MA-25: Discrete, continuous or stochastic optimization and control in networks, transportation and design I (011 (building: 208)) | 18 |
| MA-26: Combinatorial optimization topics in transportation (012 (building: 208)) | 19 |
| MA-28: Advancements of OR-analytics in statistics, machine learning and data science 1 (065 (building: 208)) | 20 |
| MA-29: Combinatorial Optimization models and applications in Logistics and Transportation I (157 (building: 208)) | 21 |
| MA-30: MIP Solvers (064 (building: 208)) | 21 |
| MA-31: Recommender systems (046 (building: 208)) | 22 |
| MA-32: Large Scale Constrained Optimization: Algorithms and Applications (41 (building: 303A)) | 23 |
| MA-33: Optimal control in supply chain management (42 (building: 303A)) | 23 |
| MA-34: Optimization and learning for data science and imaging (Part I) (43 (building: 303A)) | 24 |
| MA-35: Robust and Stochastic Routing Problems (44 (building: 303A)) | 25 |
| MA-36: Game Theory, Solutions and Structures I (32 (building: 306)) | 25 |
| MA-41: Vector and Set Optimization I (97 (building: 306)) | 26 |
| MA-42: Hybrid Classical-Quantum Algorithms (98 (building: 306)) | 26 |
| MA-43: Simulation of organizations I (99 (building: 306)) | 27 |
| MA-44: Preference Learning 1 (20 (building: 324)) | 28 |
| MA-46: Fast And Furious: Lightning Talks (40 (building: 324)) | 29 |
| MA-47: MCDA applications in Engineering and Management 1 (50 (building: 324)) | 29 |
| MA-48: DEA and its application (60 (building: 324)) | 30 |
| MA-49: Lot-sizing with joint replenishment and routing decisions (M1 (building: 101)) | 30 |
| MA-50: Food Waste (M2 (building: 101)) | 31 |
| MA-51: Risk management in finance (M5 (building: 101)) | 32 |
| MA-52: Combinatorial optimization approaches for freight deliveries and home services (8003 (building: 202)) | 32 |
| MA-54: Disruption management in passenger railways (S01 (building: 101)) | 33 |
| MA-55: Transportation Network Modelling and Optimization I (S02 (building: 101)) | 34 |

| | |
|--|----|
| MA-56: Last mile delivery modeling (S04 (building: 101)) | 34 |
| MA-57: Modelling commodity markets dynamics (S06 (building: 101)) | 35 |
| MA-58: Automated Timetabling (S07 (building: 101)) | 36 |
| MA-59: Pricing and applications 3 (S08 (building: 101)) | 36 |
| MA-60: Vehicle routing I (S09 (building: 101)) | 37 |
| MA-61: Advances in Location Analysis (S10 (building: 101)) | 38 |
| MA-62: Seaside Planning I (S12 (building: 101)) | 39 |
| MA-63: Applications in Finance and Economics (S14 (building: 101)) | 39 |
